DIVERGENCE, EXOTIC CONVERGENCE AND SELF-BUMPING IN QUASI-FUCHSIAN SPACES

KEN'ICHI OHSHIKA

Abstract. In this paper, we study the topology of the boundaries of quasi-Fuchsian spaces. We first show for a given convergent sequence of quasi-Fuchsian groups, how we can know the end invariant of the limit group from the information on the behaviour of conformal structures at infinity of the groups. This result gives rise to a sufficient condition for divergence of quasi-Fuchsian groups, which generalises Ito's result in the once-punctured torus case to higher genera. We further show that quasi-Fuchsian groups can approach b-groups not along Bers slices only when there are isolated parabolic loci. This makes it possible to give a necessary condition for points on the boundaries of quasi-Fuchsian spaces to be self-bumping points. We use model manifolds invented by Minsky and their geometric limits studied by Ohshika-Soma to prove these results.

1. Introduction

In the theory of Kleinian groups, after the major problems like Marden's tameness conjecture and the ending lamination conjecture were solved, the attention is now focused on studying the topological structure of deformation spaces. Although we know, by the resolution of the Bers-Sullivan-Thurston density conjecture ([12], [8], [32] , [22], [23], [34], [30]), that every finitely generated Kleinian group is an algebraic limit of quasi-conformal deformations of a (minimally parabolic) geometrically finite group, the structure of deformation spaces as topological spaces is far from completely understood. For instance, as was observed by work of Anderson-Canary ([2]) and McMullen ([28]), even in the case of Kleinian groups isomorphic to closed surface groups, the deformation spaces are fairly complicated, and in particular are not manifolds since they have singularities caused by a phenomenon called "bumping". Actually, this kind of phenomenon also makes the deformation space not locally connected as was shown by Bromberg [13] and generalised by Magid [24].

The interior of a deformation space is known to be a union of quasi-conformal deformation spaces of minimally parabolic Kleinian groups, which is well understood by work of Ahlfors, Bers, Kra, Maskit, Marden, and Sullivan. In particular, their theory implies that there is a parametrisation of the quasi-conformal deformation space by the Teichmüller space of the boundary at infinity of the quotient hyperbolic 3-manifold. Therefore, to understand the global structure of a deformation space, what we need to know is how the boundary is attached to the quasi-conformal deformation space. More concretely, we need to determine, for a sequence of quasi-conformal deformations given as a sequence in the Teichmüller space using this parametrisation, first whether it converges or not, and if it converges what is the

limit of the sequence. Also, we need to know in what case sequences of quasi-conformal deformations can approach the same group from different directions as in the example of Anderson-Canary and McMullen. This paper tries to answer such problems for the case of Kleinian surface groups using the technique of model manifolds of geometric limits which we developed in Ohshika-Soma [35].

The interior of a deformation space of Kleinian surface group $AH(S)$ is the quasi-Fuchsian space $QF(S)$. The parametrisation in this case is the Ahlfors-Bers map qf from $\mathcal{T}(S) \times \mathcal{T}(\bar{S})$ to $QF(S)$ giving the Ahlfors-Bers parametrisation. The celebrated work of Bers on compactifying the Teichmüller space ([4]) shows that in $AH(S)$, the subspace of $QF(S)$ in the form $\mathcal{T}(S) \times \{\text{pt.}\}$ or $\{\text{pt.}\} \times \mathcal{T}(\bar{S})$ is relatively compact. Considering a quite different direction in $QF(S)$ (with respect to the parametrisation of Ahlfors-Bers) from that of Bers, Thurston proved that a sequence $\{(m_i, n_i)\} \in \mathcal{T}(S) \times \mathcal{T}(\bar{S})$ converges if $\{m_i\}$ converges to a projective lamination $[\lambda]$ and $\{n_i\}$ converges to $[\mu]$ both in the Thurston compactification of the Teichmüller space such that every component of $S \setminus (\lambda \cup \mu)$ is simply connected ([39]).

In contrast to these results on convergence, we showed in ([33]) that if $\{m_i\}$ and $\{n_i\}$ converge to arational laminations with the same support, then $\{qf(m_i, n_i)\}$ always diverges. Since the Teichmüller space of S is properly embedded in $AH(S)$ as a diagonal set of $\mathcal{T}(S) \times \mathcal{T}(\bar{S})$, this may look very natural. However, there is an example by Anderson-Canary in [2] which shows that for a given hyperbolic structure m_0, if we consider $(\tau^i(m_0), \tau^{2i}(m_0)) \in \mathcal{T}(S) \times \mathcal{T}(\bar{S})$, where τ denotes the deformation of the metric induced by the Dehn twist around a simple closed curve γ on S, then its image $qf(\tau^i(m_0), \tau^{2i}(m_0))$ in $AH(S)$ converges. These two results show us the situation is quite different depending on the types of the limit projective laminations.

In the case when $\mathcal{T}(S)$ has dimension 2, i.e., if S is either a once-punctured torus or a four-time punctured sphere, a measured lamination is either arational or a weighted simple closed curve, which means that there is nothing between these two situations above. In this case, Ito has given a complete criterion for convergence/divergence ([20]). In the general case when $\mathcal{T}(S)$ has dimension more than 2 however, there is a big room between these two extremes.

Therefore quite naturally, we should ask ourselves what would happen in the cases in between. One of our main theorems in this paper (Theorem 3) is an answer to this question. Consider sequences $\{m_i\}$ in $\mathcal{T}(S)$ and $\{n_i\}$ in $\mathcal{T}(\bar{S})$ converging to $[\mu^+]$ and $[\mu^-]$ such that their supports $|\mu^+|$ and $|\mu^-|$ share a component which is not a simple closed curve. We shall prove that $\{qf(m_i, n_i)\}$ diverges in $AH(S)$ in this setting. More generally, we shall show that if μ^+ and μ^- have components μ_0^+, μ_0^- whose minimal supporting surfaces share a boundary component, then $\{qf(m_i, n_i)\}$ diverges.

This theorem is derived from another of our main results, Theorem 2, which asserts that if $\{qf(m_i, n_i)\}$ converges, then we can determine the ending laminations of the limit group by considering the shortest pants decomposition of m_i and n_i and their Hausdorff limits. It also implies Theorem 1 stating that if we consider the limit of $\{m_i\}$ and $\{n_i\}$ in the Thurston compactification of the Teichmüller space, then every non-simple-closed-curve component of the limit of $\{m_i\}$ is an ending lamination of an upper end of the limit, and every non-simple-closed-curve component of the limit of $\{n_i\}$ is that of a lower end. For a simple closed curve contained in the limit of $\{m_i\}$ not contained in that of $\{n_i\}$ is a core curve of the parabolic locus of the limit group. A similar thing holds for a simple closed curve in the limit of $\{n_i\}$ not contained that of $\{m_i\}$. These combined with Theorem 6 can be regarded as a partial answer to the problem of determining limit groups of sequence of quasi-Fuchsian groups given in terms of the parametrisation by the Teichmüller spaces.

In the case when the laminations $|\mu^+|$ and $|\mu^-|$ share only simple closed curves, the convergence or divergence of the sequence depends on whether there is a shared component which is contained in the minimal supporting surfaces of other components of $|\mu^+|$ or $|\mu^-|$. Theorem 5 asserts that if there is such a simple closed curve component, then the sequence diverges. Even in the case when such a component does not exist, $\{qf(m_i, n_i)\}$ can converge only in a special situation which is analogous to an example of Anderson-Canary [2]. Theorem 6 describes the situation where the sequence can converge. We should note that these are the best possible answers for divergence and convergence for sequence of quasi-Fuchsian groups when the asymptotic behaviour of the corresponding parameters are expressed in terms of the Thurston compactification of Teichmüller spaces.

The same example of Anderson-Canary also shows that there is a point in $AH(S)$ where $QF(S)$ bumps itself as explained above. In such a point, the self-bumping is caused by what is called the "exotic convergence". A sequence of quasi-Fuchsian group is said to converge to a b-group exotically when the groups in the sequence are not contained in Bers slices approaching the one containing the limit b-group. The construction of Anderson-Canary gives a sequence converging exotically to a regular b-group. We shall prove such a convergence cannot occur for b-groups which do not have $\mathbb{Z}$-cusps not touching geometrically infinite ends.

As for self-bumping, we conjecture that such a phenomenon cannot happen for geometrically infinite b-groups all of whose $\mathbb{Z}$-cusps touch geometrically infinite ends. What we shall prove is a weaker form of this conjecture: We shall show that if there are two sequences $\{qf(m_i, n_i)\}$ and $\{qf(m_i', n_i')\}$ both converging to the same geometrically infinite group all of whose $\mathbb{Z}$-cusps touch geometrically infinite ends, then for any small neighbourhood U of the quasi-conformal deformation space of the limit group, if we take large i, then $qf(m_i, n_i)$ and $qf(m_i', n_i')$ are connected by an arc in U. In particular this shows that under the same condition on $\mathbb{Z}$-cusps, if the limit group is either quasi-conformally rigid or a b-group whose upper conformal structure at infinity is rigid, it cannot be a self-bumping point. More generally, even when there is a cusp not touching a geometrically infinite end, the same argument shows that a Bers slice cannot bump itself at a b-group whose upper conformal structure at infinity is rigid. This latter result has been obtained independently by Brock-Bromberg-Canary-Minsky [9] by a different approach.

Finally, in Theorems 11 and 12, we shall generalise the results for quasi-Fuchsian groups in Theorems 2 and 3 to general surface Kleinian groups.

Our tools for proving all these theorems are model manifolds invented by Minsky [29] and their geometric limits studied in Ohshika-Soma [35]. The technique which we develop in this paper shows that model manifolds are quite useful for studying the asymptotic behaviour of sequence in deformation spaces.

2. Preliminaries

2.1. **Generalities.** Kleinian groups are discrete subgroups of $\mathrm{PSL}_2\mathbb{C}$. In this paper we always assume Kleinian groups to be torsion free. When we talk about deformation spaces, we only consider finitely generated Kleinian groups. However, we also need to consider infinitely generated Kleinian groups which will appear as geometric limits. We refer the reader to Marden [25] for a general references for the theory of Kleinian groups.

Let S be an orientable hyperbolic surface of finite area. In this paper, we focus on Kleinian groups which are isomorphic to $\pi_1(S)$ in such a way parabolic elements correspond to punctures of S. We define a deformation space $AH(S)$ to be the quotient space of

$$\begin{aligned} R(S) = \quad & \{(G,\phi) \mid \phi : \pi_1(S) \to \mathrm{PSL}_2\mathbb{C} \text{ is a faithful discrete representation} \\ & \quad \text{preserving the parabaolicity with } \phi(\pi_1(S)) = G\} \end{aligned}$$

by conjugacy in $\mathrm{PSL}_2\mathbb{C}$. The space $R(S)$ has a topology coming from the representation space and we endow $AH(S)$ with its quotient topology. We denote an element of $AH(S)$ also by (G,ϕ) for some representative of the equivalence class. We call ϕ a marking of the Kleinian group G.

The set of faithful discrete representations of $\pi_1(S)$ into $\mathrm{PSL}_2\mathbb{R}$ modulo conjugacy constitutes the Teichmüller space of S, which we denote by $\mathcal{T}(S)$. Then, $\mathcal{T}(S)$ is naturally contained in $AH(S)$. More generally, the space of quasi-Fuchsian groups $QF(S)$ lies in $AH(S)$. A quasi-Fuchsian group is a Kleinian group whose domain of discontinuity is a disjoint union of two simply connected components. By the theory of Ahlfors-Bers, $QF(S)$ is parametrised by a homeomorphism $qf : \mathcal{T}(S) \times \mathcal{T}(\bar{S}) \to QF(S)$. Here both $\mathcal{T}(S)$ and $\mathcal{T}(\bar{S})$ are the Teichmüller space of S, but the latter one is identified with $\mathcal{T}(S)$ by an orientation reversing autohomeomorphism of S. For $(m,n) \in \mathcal{T}(S) \times \mathcal{T}(\bar{S})$, its image $qf(m,n)$ is obtained by starting from a Fuchsian group and solving a Beltrami equation so that the conformal structure on the quotient of the lower Jordan domain is m and that on the quotient of the upper Jordan domain is n. We call m and n the lower and upper *conformal structures at infinity* of $qf(m,n)$ respectively. The set of Fuchsian groups corresponds to a slice of the form $\{qf(m,m)\}$. By the theory of Ahlfors-Bers combined with Sullivan's rigidity [37], we know that $QF(S)$ is the interior of the entire deformation space $AH(S)$. On the other hand, the Bers-Sullivan-Thurston density conjecture, which was solved by Bromberg [7], Brock-Bromberg [8] in this setting, or is obtained as a corollary of the ending lamination conjecture [10] combined with [31], $AH(S)$ is the closure of $QF(S)$.

By Margulis' lemma, there is a positive constant ϵ_0 such that for any hyperbolic 3-manifold, its ϵ_0-thin part is a disjoint union of cusp neighbourhoods and tubular neighbourhoods of short closed geodesics, which are called Margulis tubes. For a hyperbolic 3-manifold M, we denote by M_0 the complement of its cusp neighbourhoods.

Bonahon showed in [6] that for any $(G,\phi) \in AH(S)$, the hyperbolic 3-manifold $\mathbb{H}^3/G$ is homeomorphic to $S \times (0,1)$. We denote by Φ a homeomorphism from $S \times (0,1)$ to $\mathbb{H}^3/G$ inducing ϕ between the fundamental groups. In general, for an element in $AH(S)$, we denote a homeomorphism from $S \times (0,1)$ to the quotient hyperbolic 3-manifold by the letter in the upper case corresponding to a Greek letter denoting the marking. Bonahon also proved the every end of $(\mathbb{H}^3/G)_0$ is either geometrically finite or simply degenerate. Here an end is called *geometrically finite* if it has a neighbourhood which is disjoint from any closed geodesic, and *simply degenerate* if it has a neighbourhood of the form $\Sigma \times (0, \infty)$ for an incompressible subsurface Σ of S and there is a sequence of simple closed curves $\{c_n\}$ on Σ which are homotopic to closed geodesics c_n^* going to the end. For a simply degenerate end, the *ending lamination* is defined to be the support of the projective lamination to which $[c_n]$ converges in the projective lamination space $\mathcal{PML}(\Sigma)$. We shall explain what are laminations and the projective lamination space below.

For $(G, \phi) \in AH(S)$, we choose an embedding $f : S \to \mathbb{H}^3/G$ inducing ϕ between the fundamental groups. Such an embedding is unique up to ambient isotopy in $\mathbb{H}^3/G$. An end of $\mathbb{H}^3/G$ is called *upper* when it lies above $f(S)$ and *lower* when it lies below $f(S)$. Let C be a compact core of $(\mathbb{H}^3/G)_0$ intersecting each component of $\mathrm{Fr}(\mathbb{H}^3/G)_0$ by a core annulus. Let P denote $C \cap \mathrm{Fr}(\mathbb{H}^3/G)_0$. Each component of P is called a *parabolic locus* of $\mathbb{H}^3/G$ or C. Parabolic loci corresponding to punctures of S are called *boundary parabolic loci*. For non-boundary parabolic loci, those contained in $S \times \{1\}$ are called upper and those contained in $S \times \{0\}$ lower. The ends of $(\mathbb{H}^3/G)_0$ correspond one-to-one to the components of $\mathrm{Fr}C$. Since C is homeomorphic to $S \times [0, 1]$, each upper end faces a subsurface of $S \times \{1\}$, which is a component of $S \times \{1\} \setminus P$. A non-boundary parabolic locus p in P is called *isolated* when the components of $S \times \{0, 1\} \setminus P$ adjacent to p (there are one or two such components) face geometrically finite ends, in other words, no component of $S \times \{0, 1\} \setminus P$ facing a simply degenerate end touches p at its frontier.

2.2. **Laminations.** A geodesic lamination on a hyperbolic surface S is a closed subset of S consisting of disjoint geodesics, which are called leaves. For a geodesic lamination λ, each component of $S \setminus \lambda$ is called a complementary region of λ. We say that a geodesic lamination is *arational* when every complementary region is simply connected. A subset l of a geodesic lamination is called a *minimal component* when for each leaf ℓ of l, its closure $\bar{\ell}$ coincides with l. Any geodesic lamination is decomposed into finitely many minimal components and finitely many non-compact isolated leaves.

A measured lamination is a (possibly empty) geodesic lamination endowed with a transverse measure which is invariant with respect to a homotopy along leaves. The support of the transverse measure of a measured lamination μ, which is a geodesic lamination, is called the support of μ and is denoted by $|\mu|$. When we consider a measured lamination, we always assume that its support is the entire lamination. The measured lamination space $\mathcal{ML}(S)$ is the set of measured laminations on S endowed with the weak topology. Thurston proved that $\mathcal{ML}(S)$ is homeomorphic to $\mathbb{R}^{6g-6+2p}$, where g is the genus and p is the number of punctures. A weighted disjoint union of closed geodesics can be regarded as a measured lamination. It was shown by Thurston that the set of weighted disjoint unions of closed geodesics is dense in $\mathcal{ML}(S)$.

The projective lamination space $\mathcal{PML}(S)$ is the space obtained by taking a quotient of $\mathcal{ML}(S) \setminus \{\emptyset\}$ identifying scalar multiples. Thurston constructed a natural compactification of the Teichmüller space whose boundary is $\mathcal{PML}(S)$ in such a way that the mapping class group acts continuously on the compactification.

We need to consider one more space, the unmeasured lamination space. This space, denoted by $\mathcal{UML}(S)$, is defined to be the quotient space of $\mathcal{ML}(S)$, where two laminations with the same support are identified. An element in $\mathcal{UML}(S)$ is called an unmeasured lamination.

For a minimal geodesic lamination λ on S, its *minimal supporting surface* is defined to be a subsurface of S with geodesic boundary containing λ which is minimal among all such surfaces. When λ is a closed geodesic, we define its minimal supporting surface to be λ itself. It is obvious the minimal supporting surface of λ is uniquely determined.

2.3. **Algebraic convergence and geometric convergence.** When $\{(G_i, \phi_i)\}$ converges to $(\Gamma, \psi) \in AH(S)$, we say that the sequence converges *algebraically* to (Γ, ψ). We can choose representatives (G_i, ϕ_i) so that ϕ_i converges to ψ as representations. As a convention, when we say that $\{(G_i, \phi_i)\}$ converges to (Γ, ψ), we always take representatives so that $\{\phi_i\}$ converges to ψ.

We need to consider another kind of convergence, the geometric convergence. A sequence of Kleinian groups $\{G_i\}$ is said to converge to a Kleinian group G_∞ *geometrically* if (1) for any convergent sequence $\{\gamma_{i_j} \in G_{i_j}\}$, its limit lies in G_∞, and (2) any element $\gamma \in G_\infty$ is a limit of some $\{g_i \in G_i\}$. When (G_i, ϕ_i) converges to (Γ, ψ) algebraically, the geometric limit G_∞ contains Γ as a subgroup.

When $\{G_i\}$ converges to G_∞ geometrically, if we take a basepoint x in $\mathbb{H}^3$ and its projections $x_i \in \mathbb{H}^3/G_i$ and $x_\infty \in \mathbb{H}^3/G_\infty$, then $(\mathbb{H}^3/G_i, x_i)$ converges to $(\mathbb{H}^3/G_\infty, x_\infty)$ with respect to the pointed Gromov-Hausdorff topology: that is, there exists a (K_i, r_i)-approximate isometry $B_{r_i}(\mathbb{H}^3/G_i, x_i) \to B_{K_i r_i}(\mathbb{H}^3/G_\infty, x_\infty)$ with $K_i \to 1$ and $r_i \to \infty$.

2.4. **Bers slices and b-groups.** We fix a point $m_0 \in \mathcal{T}(S)$ and consider a subspace $qf(\{m_0\} \times \mathcal{T}(\bar{S}))$ in $QF(S)$. This space is called the *Bers slice* over m_0. Kleinian groups lying on its frontier are called *b-groups* with lower conformal structure m_0.

Anderson-Canary [2] constructed a sequence of quasi-Fuchsian groups converging to a b-group whereas its coordinates in $QF(S)$ do not approach a Bers slice.

Definition 2.1. We say a sequence of quasi-Fuchsian groups $\{(G_i, \phi_i) = qf(m_i, n_i)\}$ converges *exotically* to a b-group (Γ, ψ) if $\{(G_i, \phi_i)\}$ converges to (Γ, ψ) algebraically and both $\{m_i\}$ and $\{n_i\}$ go out from any compact set in the Teichmüller space.

The existence of exotic convergence is related to the singularities of $AH(S)$ at its boundary. In fact, McMullen showed in [28] that $AH(S)$ has a singular point at infinity where $QF(S)$ bumps itself. For a Kleinian surface group $(\Gamma, \psi) \in AH(S) \setminus QF(S)$, we say that $QF(S)$ *bumps itself* at (Γ, ψ), when there is a neighbourhood V of (Γ, ψ) such that for any smaller neighbourhood $U \subset V$, its intersection with the quasi-Fuchsian space, $U \cap QF(S)$ is disconnected. McMullen showed the existence of points where $QF(S)$ bumps itself, making use of the construction of Anderson-Canary.

We say that a Bers slice $\mathcal{B}(m_0) = qf(\{m_0\} \times \mathcal{T}(\bar{S}))$ bumps itself at (Γ, ψ) when there is a neighbourhood V of (Γ, ψ) such that for any smaller neighbourhood $U \subset V$, its intersection with the Bers slice, $U \cap \mathcal{B}(m_0)$ is disconnected. Up to now, it is not known if a Bers slice can bump itself or not.

2.5. **Curve complexes and hierarchies.** In the theory of hierarchies invented by Masur-Minsky [27], we need to consider subsurfaces of a fixed surface S. We say a subsurface is *essential* when it is a proper subsurface and each of its frontier component is a non-contractible, non-peripheral curve on S. When we talk about curve complexes, we usually regard essential subsurfaces as open subsurfaces without boundary, and call them *domains* of S. For a surface S of genus g and p punctures, we define $\xi(S)$ to be $3g+p$. We shall define curve complexes for orientable surfaces S with $\xi(S) \geq 4$ or $\xi(S)=2$. The *curve complex* $\mathcal{CC}(S)$ of S with $\xi(S) \geq 5$ is defined as follows. (This notion was first introduced by Harvey [19].) The vertices of $\mathcal{CC}(S)$, whose set we denote by $\mathcal{CC}_0(S)$, are the homotopy classes of essential simple closed curves on S. A set of $n+1$ vertices $\{v_0, \dots, v_n\}$ spans an n-simplex if and only if they can be represented as pairwise disjoint simple closed curves on S.

In the case when $\xi(S)=4$, the curve complex is a 1-dimensional simplicial complex. The vertices are the homotopy classes of essential simple closed curves as in the case when $\xi(S) \geq 5$. Two vertices v_0, v_1 are connected by an edge if their intersection number is 1 when S is a once-punctured torus, and 2 when if S is a four-times-punctured sphere. In the case when $\xi(S)=2$, we consider a compactification of S to an annulus. The curve complex is a 1-dimensional and the vertices are the homotopy classes (relative to the endpoints) of essential arcs with both endpoints on the boundary. Two curves are connected by an edge if they can be made disjoint in their interiors.

A *tight sequence* in $\mathcal{CC}(S)$ with $\xi(S) \geq 5$ is a sequence of simplices $\{s_0, \dots, s_n\}$ with the first one and the last one being vertices such that for any vertices $v_i \in s_i$ and $v_j \in s_j$, we have $d_{\mathcal{CC}(S)}(v_i, v_j) = |j-i|$, and s_{j+1} is homotopic to the union of essential boundary components of a regular neighbourhood of $s_j \cup s_{j+2}$. We also consider an infinite tight sequence such as $\{s_0, \dots\}$ or $\{\dots, s_0\}$ or $\{\dots, s_0, \dots\}$. In the case of surface with $\xi(S)=2,4$, we consider a sequence of vertices and ignore the second condition.

For an essential simple closed curve c of S, we consider the covering A_c of S associated to the image of $\pi_1(c)$, which is an open annulus. If we fix a hyperbolic metric on S, we can compactify the hyperbolic annulus A_c to an annulus $\bar{A}_c$ by regarding $\pi_1(c)$ as acting on $\mathbb{H}^2$ and considering the quotient of $\mathbb{H}^2 \cup \Omega_{\pi_1(c)}$ by $\pi_1(c)$. We call an essential simple arc with endpoints on $\partial \bar{A}_c$ a transversal of c. A simple closed curve d intersecting c essentially induces $i(c,d)$ transversals on c. Any two transversals induced from d are within distance 1 in $\mathcal{CC}(A_c)$.

For a non-annular domain Σ in S, we define $\pi_\Sigma : \mathcal{CC}_0(S) \to \mathcal{CC}(\Sigma) \cup \{\emptyset\}$ to be a map sending $c \in \mathcal{CC}_0(S)$ to simple closed curves obtained by connecting the endpoints of each component of $c \cap \Sigma$ by arcs on $\mathrm{Fr}\Sigma$ in a consistent way if c intersects Σ essentially. Otherwise we define $\pi_\Sigma(c)$ to be $\emptyset$. When Σ is an annulus we define $\pi_\Sigma(c)$ to be the lift of c to $\bar{\Sigma}$ if c intersects Σ essentially. (See §2.3 of Masur-Minsky [27] for details.)

A *marking* μ on a surface S consists of a simplex in $\mathcal{CC}(S)$ and transversals on some of its vertices (at most one for each). The vertices of the simplex are called the base curves of μ, and their union is denoted by $\mathrm{base}(\mu)$. A marking μ is said to be *clean* if every component c of $\mathrm{base}(\mu)$ has a transversal and it is induced by a simple closed curve with intersection number 1 when c is non-separating and with intersection number 2 if c is separating, which is disjoint from the other components of $\mathrm{base}(\mu)$. A clean marking μ' is said to be compatible with a marking μ when $\mathrm{base}(\mu) = \mathrm{base}(\mu')$, and every transversal of a component c in μ is within distance

2 from the transversal of c in μ' as vertices in the curve complex of an annulus with core curve c. A marking is called *complete* if its base curves constitute a pants decomposition of S.

To deal with the case of geometrically infinite groups, we need a notion of generalised markings. A *generalised marking* consists of an unmeasured lamination on S and transversals on some of its components which are simple closed curves. Also for a generalised marking μ, we denote the lamination by $\mathrm{base}(\mu)$. We say that a generalised marking *complete*, if its base lamination is maximal, i.e. it is not a proper sublamination of another unmeasured lamination. From now on, we always assume *markings and generalised markings to be complete.*

A finite *tight geodesic* on a surface Σ is a triple $(g, I(g), T(g))$, where g is a tight sequence and $I(g)$ and $T(g)$ are generalised markings on Σ which have at least one simple closed curve component, such that the first vertex is a simple closed curve component of the $\mathrm{base}(I(g))$ and the last vertex is that of $\mathrm{base}(T(g))$. The surface Σ is called the support of g and we write $\Sigma = D(g)$. An infinite tight geodesic is defined similarly just letting $T(g)$ be an arational unmeasured lamination to which s_i converges as $i \to \infty$ when g is in the form of $\{s_0, \dots\}$. Similarly, by letting $I(g)$ be an arational unmeasured lamination to which s_i converges as $i \to -\infty$ when g is in the form of $\{\dots, s_0\}$, and by letting both $I(g)$ and $T(g)$ be arational unmeasured laminations which are limits of s_i as $i \to -\infty$ and as $i \to \infty$ respectively when g is in the form of $\{\dots, s_0, \dots\}$. Refer to the following subsection form more explanations on the boundary of $\mathcal{CC}(\Sigma)$.

We call an open subsurface of S whose frontier is non-contractible and non-peripheral, a domain. Let Σ be a domain of S. For a simplex s in $\mathcal{CC}(\Sigma)$, its component domains are defined to be the components of $\Sigma \setminus s$ and annuli whose core curves are components of s. We consider only one annulus for each component of s. Let g be a tight geodesic in $\mathcal{CC}(\Sigma)$, and suppose that s is a simplex on g. Let Σ' be a component domain of s. (Such a domain is also said to be a component domain of g.) Then, following Masur-Minsky [27], we define $T(\Sigma', g)$ to be $\mathrm{succ}(s)|\Sigma'$ if s is not the last vertex of g, and to be $T(g)|\Sigma'$ if s is. Similarly, we define $I(\Sigma', g)$ to be $\mathrm{prec}(s)|\Sigma'$ if s is not the first vertex of g, and to be $I(g)|\Sigma'$ if s is. We write $\Sigma' \overset{d}{\searrow} g$ or $\Sigma' \overset{d}{\searrow} (g, s)$, if $T(\Sigma', g)$ is non-empty, and $g \overset{d}{\swarrow} \Sigma'$ or $(g, s) \overset{d}{\swarrow} \Sigma'$ if $I(\Sigma', g)$ is non-empty. If a geodesic k is a tight geodesic supported on Σ' with $(g, s) \overset{d}{\swarrow} \Sigma'$ and $I(k) = I(\Sigma', g)$, then we write $g \overset{d}{\swarrow} k$ or $(g, s) \overset{d}{\swarrow} k$, and say that k is *directly backward subordinate* to g at s. Similarly, if $\Sigma' \overset{d}{\searrow} (g, s)$ and $T(k) = T(\Sigma', g)$, we write $k \overset{d}{\searrow} g$ or $k \overset{d}{\searrow} (g, s)$, and say that k is *directly forward subordinate* to g at s.

A *hierarchy* h on S, which was introduced by Masur-Minsky [27], is a family of tight geodesics supported on domains of S having the following properties.

(1) There is a unique geodesic g_h supported on S.

(2) For any $g \in h$ other than g_h, there are geodesics $b, f \in h$ with $b \overset{d}{\swarrow} g \overset{d}{\searrow} f$.

(3) For any $b, f \in h$ and a component domain Σ of b, f with $b \overset{d}{\swarrow} \Sigma \overset{d}{\searrow} g$ (b and f may coincide), there is a unique geodesic k supported on Σ with $b \overset{d}{\swarrow} k \overset{d}{\searrow} f$.

A hierarchy h is said to be *complete* if every component domain of geodesics in h supports a geodesic in h, and 4-*complete* if every non-annular component domain of geodesics in h supports a geodesic in h.

In our argument, it will be necessary to loose a condition imposed on hierarchies slightly. In the definition above, for any geodesic $g \in h$, its first and last simplices are assumed to be vertices. We loose this condition for the main geodesic and geodesics subordinate to the first or the last simplex of another geodesic. To be more precise, a geodesic g in h can have the first simplex which is not a vertex if either g is the main geodesic or $(g', v) \overset{d}{\swarrow} g$ with the first simplex v of g', and g can have the last simplex which is not a vertex if either g' is the main geodesic or $g \overset{d}{\searrow} (g', v)$ with the last simplex v of g'. We call such h (satisfying all the other conditions for a hierarchy) a *generalised hierarchy*. Note that we are *not* saying that there is a generalised hierarchy connecting any given pairs of simplices. (It is easy to construct a counter-example.) In the situation where we need to consider a generalised hierarchy, its existence is guaranteed by construction. Once a generalised hierarchy exits, it is easy to check that all the constructions of slices, resolutions, and model manifolds work in the same way as in the case of a hierarchy.

We write $g \searrow (f, v)$ if there is a sequence of geodesics in h such that $g = f_0 \overset{d}{\searrow} f_1 \overset{d}{\searrow} \dots \overset{d}{\searrow} (f_n, v) = (f, v)$, and say that g is forward subordinate to f. Similarly, we write $(b, u) \swarrow g$ if there is a sequence in h such that $(b, u) = (b_m, u) \overset{d}{\swarrow} \dots \overset{d}{\swarrow} b_1 \overset{d}{\swarrow} b_0 = g$, and say that g is backward subordinate to b. We use symbol $\underset{=}{\searrow}$ to mean either $\searrow$ or $=$ and $\underset{=}{\swarrow}$ to mean either $\swarrow$ or $=$.

In §9, we shall use the notions of slices and resolutions of hierarchies invented by Masur-Minsky [27]. We shall review them briefly here. Let h be a complete or 4-complete hierarchy. A *slice* σ of h is a set of pairs (g, v), where g is a geodesic in h and v is a simplex on g satisfying the following conditions. (Masur and Minsky call σ satisfying the first three conditions a slice, and call it a complete slice if it also satisfies the fourth condition.)

1. A geodesic can appear at most in one pair of σ.
2. There is a pair whose first entry is the main geodesic of h.
3. For each pair (g, v) in σ such that g is not the main geodesic, $D(g)$ is a component domain of a simplex v' for some $(g', v') \in \sigma$.
4. For each component domain D of v for $(g, v) \in \sigma$ with $\xi(D) \neq 3$ if h is complete and $\xi(D) > 3$ if h is 4-complete, there is a pair $(g', v') \in \sigma$ with $D(g') = D$.

Masur and Minsky introduced orders $\prec_p$ between pairs of geodesics and simplices in h and $\prec_s$ between slices. For two pairs (g, v) and (g', v') of a 4-complete hierarchy, we write $(g, v) \prec_p (g', v')$ if either $g = g'$ and v' comes after v, or there is a geodesic g'' with $(g, v) \underset{=}{\searrow} (g'', w)$ and $(g'', w') \underset{=}{\swarrow} (g', v')$ such that w' is a simplex coming after w. For two distinct slices σ and τ, we write $\sigma \prec_s \tau$ if for any $(g, v) \in \sigma$, either $(g, v) \in \tau$ or there is $(g', v') \in \tau$ with $(g, v) \prec_p (g', v')$.

A *resolution* $\tau = \{\sigma_i\}$ of a 4-complete hierarchy h is an ordered sequence of slices of h such that σ_{i+1} is obtained from σ_i by an elementary forward move. An elementary forward move is a change of pairs in σ_i: We advance $(g, v) \in \sigma_i$ to

$(g, \mathrm{succ}(v))$ under the condition that for every pair (g', v') supported on a component domain of v into which $\mathrm{succ}(v)$ is projected to an essential curve, the simplex v' is the last vertex, and after removing all such (g', v') we add pairs (g'', v'') such that g'' is supported on a component domain of $\mathrm{succ}(v)$ into which v is projected to an essential curve and v'' is the first vertex of g''.

A model manifold for a Kleinian surface group is constructed in Minsky [29] as follows. Let G be a Kleinian group with $M = \mathbb{H}^3/G$. From an end invariant G, we shall construct a hierarchy of tight geodesics, h_G. A clean marking is called shortest with respect to a conformal structure if its base curve is a shortest pants decomposition and transversal are chosen to be shortest among all of those having the same base curves, where we consider the lengths to be the hyperbolic ones. In the case when G is quasi-Fuchsian, we construct a hierarchy by defining the initial and terminal markings to be the shortest clean markings with respect to the upper and lower conformal structures at infinity. When M has a totally degenerate end without accidental parabolics, we define the initial or terminal generalised marking to be its ending lamination. In general, we consider the union of ending laminations of M_0, parabolic loci for upper or lower ends, and shortest markings on the remaining geometrically finite upper or lower ends, and let them be terminal or initial generalised markings.

Then, we construct a resolution $\{\tau_i(G)\}$ of h_G. In the resolution, we look at each step $\tau_i(G) \to \tau_{i+1}(G)$ that advances a vertex on a 4-geodesic, from w_i to w_{i+1}. For such a step, we provide a block, which is topologically homeomorphic to $\Sigma \times I$, where Σ is either a sphere with four holes or a torus with one hole. The block has two ditches, one on the top and the other on the bottom, corresponding to the two vertices w_i and w_{i+1}. The top and bottom boundary of a block consists of pairs of sphere with three holes. The model manifold is constructed by piling up such blocks by pasting a top component of one block to a bottom component of another, according to the information given by the resolution $\{\tau_i(G)\}$, attach *boundary blocks* to the top and the bottom of the piled up blocks if there are geometrically finite ends of M_0, which have special forms and are constructed according to conformal structures at infinity of G, and then finally fill in Margulis tubes. In this paper, we let a boundary block have a form $\Sigma \times [s, t)$ or $\Sigma \times (t, s]$ for some subsurface Σ of S, and do not put extra-annuli as in Minsky's definition. This is because we are constructing a model manifold of the *non-cuspidal part*, not of the entire manifold. By the same reason, in contrast to Minsky's original construction, we do not fill in cusp neighbourhoods to make it compatible with model manifolds for geometric limits developed in [35]. Each slice in $\{\tau_i(G)\}$ corresponds to a *split level surface* in the model manifold which is a disjoint union of horizontal surfaces in blocks which are spheres with three holes. Taking split level surfaces to pleated surfaces, a homotopy equivalent map from the model manifold to M_0 is constructed. This can be modified to a uniform bi-Lipschitz map which is called *a model map* to M_0. See Minsky [29] and Brock-Canary-Minsky [10] for more details.

2.6. **The boundaries at infinity of curve complexes.** It was proved by Masur-Minsky [26] that $\mathcal{CC}(S)$ is a Gromov hyperbolic space with respect to the path metric defined by setting every edge to have the unit length. For a Gromov hyperbolic space, its boundary at infinity can be defined as a topological space. (Refer for instance to Coornaert-Delzant-Papadopoulos [16].) Klarreich in [21] showed that the boundary at infinity of $\mathcal{CC}(S)$ is the space of ending laminations: that is, the space of arational unmeasured laminations with topology induced from $\mathcal{UML}(S)$. This space is denoted by $\mathcal{EL}(S)$.

We shall show the following lemma, which is an easy consequence of the definition of the topology of $\mathcal{CC}(\Sigma) \cup \mathcal{EL}(\Sigma)$.

Lemma 2.2. *Let $\{g_i\}$ be a sequence of geodesics in $\mathcal{CC}(\Sigma)$ converging to a geodesic ray g_∞ uniformly on every compact set. Then the last vertex of g_i converges to the endpoint at infinity of g_∞ with respect to the topology of $\mathcal{CC}(\Sigma) \cup \mathcal{EL}(\Sigma)$.*

Proof. Let λ be a measured lamination whose support is the endpoint at infinity of g_∞. We can assume that all the g_i have the same initial vertex, which we denote by v. Let w_i be the last vertex of g_i. Since the length of g_i goes to infinity, the distance between v and w_i goes to infinity. On the other hand, since $\{g_i\}$ converges to g_∞ on every compact set, there is a number $n_{i,j}$ going to ∞ such that the first $n_{i,j}$ simplices of g_i and g_j are the same. Since $(w_i|w_j)_v \geq n_{i,j}$, we see that $(w_i|w_j)_v$ goes to ∞ as $i, j \to \infty$. Therefore, $\{w_i\}$ converges to some ending lamination after passing to a subsequence. By the definition of the topology on $\mathcal{CC}(\Sigma) \cup \mathcal{EL}(\Sigma)$, there is a measured lamination μ and positive real numbers r_i such that $\{r_i w_i\}$ converges to μ.

We need to show that $|\mu| = |\lambda|$. Suppose not. Since $\{g_i\}$ converges to g_∞ uniformly on every compact set, we can take a simplex $v_i \in g_\infty$ which is also contained in g_i tending to $|\lambda|$ in $\mathcal{CC}(\Sigma) \cup \mathcal{EL}(\Sigma)$. Since $|\lambda|$ and $|\mu|$ are distinct points on the boundary at infinity, we have $\limsup_{i\to\infty}(v_i|w_i)_v < \infty$. This contradicts the facts that both v_i and w_i lie on the same geodesic g_i and that both $d(v, v_i)$ and $d(v, w_i)$ go to ∞. □

3. The main results

In this section, we shall state our main theorems.

3.1. End invariants of limit groups.

We shall first state a theorem showing that for a limit of quasi-Fuchsian groups, the limit laminations of upper conformal structures at infinity appear as ending laminations of upper ends whereas the limit of lower ones appear as ending laminations of lower ends

Theorem 1. *Let $\{(m_i, n_i)\}$ be a sequence in $\mathcal{T}(S) \times \mathcal{T}(\bar{S})$ such that $\{qf(m_i, n_i)\}$ converges to (Γ, ψ) in $AH(S)$. Let $[\mu^+]$ and $[\mu^-]$ be projective laminations which are limits of $\{m_i\}$ and $\{n_i\}$ in the Thurston compactification of the Teichmüller space. Then every component of $|\mu^+|$ that is not a simple closed curve is the ending lamination of an upper end of $(\mathbb{H}^3/\Gamma)_0$ whereas every component of $|\mu^-|$ that is not a simple closed curve is the ending lamination of a lower end.*

Moreover every simple closed curve in $|\mu^+|$ that is not contained in $|\mu^-|$ is a core curve of an upper parabolic locus. Similarly every simple closed curve in $|\mu^-|$ that is not contained in $|\mu^+|$ is a core curve of a lower parabolic locus.

Simple closed curves contained both $|\mu^+|$ and $|\mu^-|$ will be dealt with in Theorem 6.

This theorem will be obtained by combining the following theorem with a simple lemma regarding the Thurston compactification of Teichmüller space.

Theorem 2. *In the same setting as in Theorem 1, let c_{m_i} and c_{n_i} be shortest pants decompositions of (S, m_i) and (S, n_i) respectively. Let ν^-, ν^+ be the Hausdorff* *limits of* $\{c_{m_i}\}$ *and* $\{c_{n_i}\}$ *respectively. Then the minimal components of* ν^+ *that are not simple closed curves coincide with the ending laminations of upper ends of* $(\mathbb{H}^3/\Gamma)_0$. *Moreover, no upper parabolic locus can intersect a minimal component of* ν^+ *transversely. Similarly the minimal components of* ν^- *that are not simple closed curves coincide with the ending laminations of lower ends of* $(\mathbb{H}/\Gamma)_0$*, and no lower parabolic locus can intersect a minimal component of* ν^- *transversely.*

3.2. **Divergence theorems.** We shall next state our theorems on divergence of quasi-Fuchsian groups. In the following theorems, we shall give sufficient conditions for sequences to diverge .

Theorem 3. *Let* $\{(m_i, n_i)\}$ *be a sequence in* $\mathcal{T}(S) \times \mathcal{T}(\bar{S})$ *satisfying the following conditions.*

1. $\{m_i\}$ *converges to a projective lamination* $[\mu^-] \in \mathcal{PML}(S)$ *whereas* $\{n_i\}$ *converges to* $[\mu^+] \in \mathcal{PML}(S)$ *in the Thurston compactification of the Teichmüller space.*
2. *There are components* μ_0^+ *of* μ^- *and* μ_0^- *of* μ^+ *which are not simple closed curves and have the minimal supporting surfaces sharing at least one boundary component.*

Then the sequence $\{qf(m_i, n_i)\} \subset QF(S)$ *diverges in* $AH(S)$.

Theorem 3 follows rather easily from Theorem 1. If we use Theorem 2 instead of Theorem 1, we get the following.

Theorem 4. *Let* $\{m_i\}$ *and* $\{n_i\}$ *be sequences in* $\mathcal{T}(S)$ *and* $\mathcal{T}(\bar{S})$ *without convergent subsequences, and let* c_{m_i} *and* c_{n_i} *be shortest pants decomposition of the hyperbolic surfaces* (S, m_i) *and* (S, n_i) *respectively. Suppose that* c_{m_i} *and* c_{n_i} *converge to* μ^- *and* μ^+ *in the Hausdorff topology respectively. Suppose that there are minimal components* μ_0^- *of* μ^- *and* μ_0^+ *of* μ^+ *which are not simple closed curves and have minimal supporting surfaces sharing at least one boundary component. Then* $\{qf(m_i, n_i)\} \subset QF(S)$ *diverges in* $AH(S)$.

In the setting of these theorems, the case when μ_0^- and μ_0^+ have the same support is most interesting. In fact, if they do not, it is much easier to prove the theorems just by using the continuity of length function in hyperbolic manifolds and the fact that ending lamination for a simply degenerate end is uniquely determined. Also the assumption that μ_0^- and μ_0^+ are not simple closed curves is essential. In the case when μ^- and μ^+ share simple closed curves, the construction of Anderson-Canary [2] gives an example of convergent sequence. Still, we can show the following theorem.

Theorem 5. *Let* μ^- *and* μ^+ *be two measured laminations on* S *such that the components shared by* $|\mu^-|$ *and* $|\mu^+|$ *are all simple closed curves, which we denote by* $c_1, \ldots, c_r$. *Suppose that at least one of* $c_1, \ldots, c_r$ *lies on the boundary of the minimal supporting surface of a component of either* μ^- *or* μ^+. *Then for every* $\{m_i\}$ *converging to* $[\mu^-]$ *and* $\{n_i\}$ *converging to* $[\mu^+]$ *in the Thurston compactification of the Teichmüller space, the sequence* $\{qf(m_i, n_i)\} \subset QF(S)$ *diverges in* $AH(S)$.

In the case when none of $c_1, \ldots, c_r$ lies on the boundary of minimal supporting surface of a component of μ^- or μ^+, we need to take into accounts the weights on $c_1, \ldots, c_r$, as was done in Ito [20] in the case of once-punctured torus groups.

Theorem 6. *Consider, as in Theorem 5, sequences $\{m_i\}$ and $\{n_i\}$ converging to $[\mu^-]$ and $[\mu^+]$ respectively whose supports share only simple closed curves $c_1, \ldots, c_r$. Suppose that none of $c_1, \ldots, c_r$ lies on the boundary of the minimal supporting surface of a component of μ^- or μ^+. Then $\{qf(m_i, n_i)\}$ converges after taking a subsequence only if the following conditions are satisfied.*

1. *For each c_j among $c_1, \ldots, c_r$, neither $\mathrm{length}_{m_i}(c_j)$ nor $\mathrm{length}_{n_i}(c_j)$ goes to 0.*
2. *There are sequences of integers $\{p_i^1\}, \ldots, \{p_i^r\}, \{q_i^1\}, \ldots, \{q_i^r\}$ and constants $a, b \in \mathbb{Z}$ such that the following hold after passing to a subsequence:*
   - *(a) If $|\mu^-| \setminus \cup_{j=1}^r c_j$ is non-empty, then $(\tau_{c_1}^{p_i^1} \circ \cdots \circ \tau_{c_r}^{p_i^r})_*(m_i)$ converges to $[\mu^- \setminus \cup_{j=1}^r w_j c_j]$ in the Thurston compactification, where w_j is the transverse measure on c_j in μ^- and τ_{c_j} denotes the Dehn twist around c_j. Otherwise $(\tau_{c_1}^{p_i^1} \circ \cdots \circ \tau_{c_r}^{p_i^r})_*(m_i)$ either stays in a compact set of the Teichmüller space or converges to a projective lamination $[\nu^-]$ which contains none of $c_1, \ldots, c_r$ as leaves.*
   - *(b) Similarly, if $|\mu^+| \setminus \cup_{j=1}^r c_j$ is non-empty, $(\tau_{c_1}^{q_i^1} \circ \cdots \circ \tau_{c_r}^{q_i^r})_*(n_i)$ converges to $[\mu^+ \setminus \cup_{j=1}^r v_j c_j]$ in the Thurston compactification, where v_j is the transverse measure on c_j in μ^+. Otherwise $(\tau_{c_1}^{q_i^1} \circ \cdots \circ \tau_{c_r}^{q_i^r})_*(n_i)$ either stays in a compact set of the Teichmüller space or converges in the Thurston compactification to a projective lamination $[\nu^+]$ which contains none of $c_1, \ldots, c_r$ as leaves.*
   - *(c) There exists $a_j \in \mathbb{Z}$ $(j = 1, \ldots, r)$ such that $(a_j + 1)p_i^j = a_j q_i^j$ for every $j = 1, \ldots, r$ and large i.*

In this situation, c_j is a core curve of an upper parabolic locus of the algebraic limit if $a_j \leq 0$, and that of a lower parabolic locus otherwise.

Conversely, let $a_j \in \mathbb{Z}\,(j = 1, \ldots, r)$ be any number, and μ^-, μ^+ measured laminations with the following conditions.

- *(1*) The laminations μ^- and μ^+ do not have non-simple-closed-curve minimal components μ_0^- and μ_0^+ whose minimal supporting surfaces sharing a boundary component.*
- *(2*) In the case when both μ^- and μ^+ are connected and the minimal supporting surfaces of μ^- and μ^+ are the entire surface S, the supports $|\mu^-|$ and $|\mu^+|$ do not coincide.*
- *(3*) For (possibly empty) simple closed curves $c_1, \ldots, c_r$ shared by $|\mu^-|$ and $|\mu^+|$, none of $c_1, \ldots, c_r$ lies on the boundary of the minimal supporting surface of a component of μ^- or μ^+.*

Then, there is a sequence of $\{(m_i, n_i)\}$ in $\mathcal{T}(S) \times \mathcal{T}(\bar{S})$ with algebraically convergent $\{qf(m_i, n_i)\}$ such that $\{m_i\}$ converges to $[\mu^-]$ and $\{n_i\}$ converges to $[\mu^+]$ in the Thurston compactification, and the two conditions (1) and (2) above are satisfied.

The latter half of this theorem shows that *as sufficient conditions for divergence expressed in term of the limits of the conformal structures in the Thurston compactification, Theorems 3 and 5 together with the main theorem of* [33] *are best possible.*

3.3. **Non-existence of exotic convergence.**

What Theorem 5 claims is related to the fact that such a sequence cannot converge exotically to a b-group. The condition that none of $c_1, \dots, c_r$ lies on the boundary of the supporting surface of a component of μ^- or μ^+ is essential for the exotic convergence. We can prove the following related results. (Recall that a non-boundary parabolic locus is said to be isolated if it does not touch a simply degenerate end.)

Theorem 7. *Let G be a b-group without isolated parabolic locus. Then there is no sequence of quasi-Fuchsian groups exotically converging to G.*

3.4. **Self-bumping.** As the results of McMullen [28], Bromberg [7] and Magid [24] suggest, the singularities of $AH(S)$ which are found thus far are all related to the construction of Anderson-Canary. The following results show that convergence to geometrically infinite groups in $AH(S)$ without isolated parabolic loci is quite different from the situation for regular b-groups where $QF(S)$ bumps itself.

Theorem 8. *Let Γ be a geometrically infinite group with isomorphism $\psi : \pi_1(S) \to \Gamma$ in $AH(S)$. Suppose that Γ does not have an isolated parabolic locus. Let $\{(m_i, n_i)\}$ and $\{(m_i', n_i')\}$ be two sequences in $\mathcal{T}(S) \times \mathcal{T}(\bar{S})$ such that both $\{qf(m_i, n_i)\}$ and $\{qf(m_i', n_i')\}$ converge to (Γ, ψ). Then for any neighbourhood U of the quasi-conformal deformation space $QH(\Gamma, \psi)$ of (Γ, ψ) in $AH(S)$, we can take i_0 so that if $i > i_0$, then there is an arc α_i in $U \cap QF(S)$ connecting $qf(m_i, n_i)$ with $qf(m_i', n_i')$. In the case when Γ is a b-group whose lower conformal structure at infinity is m_0, we can take α_i satisfying further the following condition. For any neighbourhood V of m_0, we can take i_0 so that for any $i > i_0$, the arc α_i is also contained in $qf(V \times \mathcal{T}(\bar{S}))$.*

We shall then get a corollary as follows.

Corollary 9. *In the setting of Theorem 8, suppose furthermore that each component of Ω_Γ/Γ that is not homeomorphic to S is a thrice-punctured sphere. Then $QF(S)$ does not bump itself at (Γ, ψ), and in particular $AH(S)$ is locally connected at (Γ, ψ).*

We can generalise this corollary by dropping the assumption that there are no isolated parabolic loci. The same result has been obtained by substantially different methods in Brock-Bromberg-Canary-Minsky [9]; see also Canary [15]. Also, a related result has been obtained by Anderson-Lecuire [3].

Corollary 10. *Let Γ be a group on the boundary of $QF(S)$ with isomorphism $\psi : \pi_1(S) \to \Gamma$. This time we allow Γ to have isolated parabolic loci.*

1. *If every component of Ω_Γ/Γ is a thrice-punctured sphere, then $QF(S)$ does not bump itself at (Γ, ψ).*
2. *If Γ is a b-group and every component of Ω_Γ/Γ corresponding to upper ends of $(\mathbb{H}^3/\Gamma)_0$ is a thrice-punctured sphere, then the Bers slice containing (Γ, ψ) on the boundary does not bump itself.*

3.5. **General Kleinian surface groups.** We can generalise Theorems 2 and 3 to sequences of Kleinian surface groups which may not be quasi-Fuchsian.

Let G be a Kleinian surface group with marking $\phi : \pi_1(S) \to G$, and set $M = \mathbb{H}^3/G$. The marking ϕ determines a homeomorphism $h : S \times \mathbb{R} \to M$. Let P_+ be the upper parabolic loci on S. We consider all the upper ends of the non-cuspidal part M_0. For a geometrically finite end, we consider its minimal pants decomposition, and for a simply degenerate end, we consider its ending lamination. Take the union of all these curves and laminations together with the core curves of P_+, and denote it by e_+. In the same way, we define e_- for the lower ends. We call e_+ and e_- the upper and lower *generalised shortest pants decompositions* respectively.

We now state a generalisation of Theorem 2

Theorem 11. *Let $\{(G_i, \phi_i)\}$ be a sequence of Kleinian surface groups which have upper and lower generalised shortest pants decompositions $e(i)_+$ and $e(i)_-$. Suppose that $\{(G_i, \phi_i)\}$ converges algebraically to (Γ, ψ). Consider the Hausdorff limit $e(\infty)_+$ of $\{e(i)_+\}$ and $e(\infty)_-$ of $\{e(i)_-\}$ after passing to subsequences. Then every minimal component of $e(\infty)_+$ (resp. $e(\infty)_-$) that is not a simple closed curve is the ending lamination of an upper end (resp. lower end) of $(\mathbb{H}^3/\Gamma)_0$. Conversely any ending lamination of an upper (resp. lower) end of $(\mathbb{H}^3/\Gamma)_0$ is a minimal component of $e(\infty)_+$ (resp. $e(\infty)_-$). Moreover, no upper (resp. lower) parabolic locus can intersect a minimal component of $e(\infty)_+$ (resp. $e(\infty)_-$) transversely.*

Next we shall state a generalisation of Theorem 3.

Theorem 12. *Let $\{(G_i, \phi_i)\}$ be a sequence of Kleinian surface groups which have upper and lower generalised shortest pants decompositions $e(i)_+$ and $e(i)_-$. Let $e(\infty)_+$ and $e(\infty)_-$ be the Hausdorff limits of $\{e_+(i)\}$ and $\{e_-(i)\}$ respectively. If there are minimal components λ of $e(\infty)_-$ and μ of $e(\infty)_+$ which are not simple closed curves and whose minimal supporting surfaces share a boundary component, then $\{(G_i, \phi_i)\}$ diverges in $AH(S)$.*

4. Models of geometric limits

4.1. **Brick decompositions of geometric limits.** In this section, we shall review the results in Ohshika-Soma [35] and show some facts derived from them, which are essential in our discussion.

Throughout this section, we assume that we have a sequence $\{(G_i, \phi_i)\}$ in $AH(S)$ converging to (Γ, ψ), and that $\{G_i\}$ converges geometrically to G_∞, which contains Γ as a subgroup. We do not assume that G_i is quasi-Fuchsian, to make our argument work also for the proofs of Theorems 11 and 12. Recall that $M_\infty = \mathbb{H}^3/G_\infty$ is a Gromov-Hausdorff limit of $M_i = \mathbb{H}^3/G_i$ with basepoints which are projections of some point fixed in $\mathbb{H}^3$. We denote $\mathbb{H}^3/\Gamma$ by M'. Let $p : M' \to M_\infty$ denote the covering associated to the inclusion of Γ to G_∞. Let $\rho_i : B_{r_i}(M_i, y_i) \to B_{K_i r_i}(M_\infty, y_\infty)$ denote an approximate isometry corresponding to the Gromov convergence of (M_i, y_i) to (M_∞, y_∞).

In [35], we introduced the notion of brick manifolds. A brick manifold is a 3-manifold constructed from "bricks" which are defined as follows. We note that a brick is an entity different from a block introduced by Minsky which we explained in Preliminaries. Still, as we shall see, in our settings each brick is decomposed into blocks.

Definition 4.1. A *brick* is a product interval bundle of the form $\Sigma \times J$, where Σ is an incompressible subsurface of S and J is a closed or half-open interval in $[0, 1]$. We assume that Σ is a closed subset of S, i.e. $\mathrm{Fr}\Sigma$ is contained in Σ. For a brick $B = \Sigma \times J$, the *lower front*, denoted by $\partial_- B$, is defined to be $\Sigma \times \inf J$, and the *upper front*, denoted by $\partial_+ B$, is defined to be $\Sigma \times \sup J$. When J is an half-open interval, one of them may not really exist, but corresponds to an end. In this case, a front is called an *ideal front*. A brick naturally admits two foliations: one is a horizontal foliation whose leaves are horizontal surfaces $\Sigma \times \{t\}$, and the other is a vertical foliation whose leaves are vertical lines $\{p\} \times J$.

A brick manifold is a manifold consisting of countably many bricks, whose boundary consists of tori and open annuli. Two bricks can intersect only at their fronts in such a way that an essential subsurface is the upper front of one brick is pasted to an essential surface in the lower front of the other brick. (We say that a subsurface is essential if none of its boundary components are null-homotopic or peripheral.)

The following is one of the main theorems of [35] which is fitted into our present situation.

Theorem 4.2 (Ohshika-Soma [35])**.** *Let $\{(G_i, \phi_i)\}$ be an algebraically convergent sequence in $AH(S)$, and M_∞ a geometric limit of $M_i = \mathbb{H}^3/G_i$ with basepoint at y_i. Then, there are a model manifold $\mathbf{M}$ of $(M_\infty)_0$, which has a structure of brick manifold, and a model map $f : \mathbf{M} \to (M_\infty)_0$ which is a K-bi-Lipschitz homeomorphism for a constant K depending only on $\chi(S)$. The model manifold $\mathbf{M}$ has the following properties.*

1. *$\mathbf{M}$ can be embedded in $S \times [0,1]$ in such a way that the vertical and horizontal foliations of the bricks are mapped into horizontal and vertical surfaces of $S \times [0,1]$ respectively.*
2. *There is no essential properly embedded annulus in $\mathbf{M}$.*
3. *An end contained in a brick is either geometrically finite or simply degenerate. The model map takes geometrically finite ends to geometrically finite ends of $(M_\infty)_0$, and simply degenerate ends to simply degenerate ends of $(M_\infty)_0$.*
4. *Every geometrically finite end of $\mathbf{M}$ corresponds to an incompressible subsurface of either $S \times \{0\}$ or $S \times \{1\}$.*
5. *An end not contained in a brick is neither geometrically finite nor simply degenerate. For such an end, there is no open annulus tending to the end which is not properly homotopic into a boundary component. We call such an end* wild.
6. *$\mathbf{M}$ has a brick of the form $S \times J$, where J is an interval containing $1/2$, and $f_\#(\pi_1(S \times \{t\}))$ with $t \in J$ carries the image of $\pi_1(M')$ in $\pi_1(M_\infty)$.*

Regard $\mathbf{M}$ as a subset of $S \times [0,1]$ which is embedded preserving the horizontal and vertical foliations. Then a brick of B has a form $\Sigma \times J$ with respect to the parametrisation of $S \times [0,1]$. We denote $\sup J$ by $\sup B$ and $\inf J$ by $\inf B$. Note that $\sup B$ is the level of the horizontal leaf on which the upper front of B lies and $\inf B$ that on which the lower front of B lies. Each end of $\mathbf{M}$, even if it is wild, corresponds to $\Sigma \times \{t\}$ for some incompressible subsurface Σ of S. By the condition (ii), every geometrically finite end is contained in either $S \times \{0\}$ or $S \times \{1\}$. We call those contained in $S \times \{0\}$ *lower geometrically finite ends* and those in $S \times \{1\}$ *upper geometrically finite ends*. By moving the embedding vertically if necessary, we can assume that $S \times \{0\}$ and $S \times \{1\}$ consist of a union of ends, annuli homotopic in $S \times [0,1] \setminus \mathrm{Int}\mathbf{M}$ to the closure of open annulus boundary components of $\mathbf{M}$, and open annuli corresponding to punctures of S.

Sometimes it is convenient to consider the complement of $\mathbf{M}$ in $S \times (0,1)$. Let B be a component of $S \times (0,1) \setminus \mathbf{M}$. Then $\mathrm{Fr}B \cap B$ consists of (countably many) horizontal surfaces each of which corresponds to an end of $\mathbf{M}$ which is either simply degenerate or wild. On the other hand, $\mathrm{Fr}B \setminus B$ consists of annuli and tori which are boundary components of $\mathbf{M}$.

We can associate to each geometrically finite end of $\mathbf{M}$ a marked conformal structure at infinity of the corresponding geometrically finite end of $(M_\infty)_0$. Similarly, we can associate to each simply degenerate end of $\mathbf{M}$ the ending lamination of the corresponding simply degenerate end of $(M_\infty)_0$. We call these conformal structures and ending laminations *labels*, and call a brick manifold with labels a *labelled brick manifold*. We showed in [35] that a labelled brick manifold is decomposed into blocks in the sense of Minsky [29] and tubes. The complement of the tubes is denoted by $\mathbf{M}[0]$. We put a metric of a Margulis tube into each tube so that the flat metric induced on the boundary coincides with that induced from the metric on $\mathbf{M}[0]$ determined by blocks.

Each Margulis tube $V = A \times [s,t]$ has a coefficient $\omega_{\mathbf{M}}(V)$ which is defined as follows. The boundary of the tube ∂V has a flat metric induced from the metric of $\mathbf{M}[0]$ determined by blocks. We can give a marking (longitude-meridian system) (α, β) to ∂V by defining α to be a horizontal curve and β to be $\partial(a \times [s,t])$ for some essential arc a connecting the two boundary components of A. The metric and the marking determine a point in the Teichmüller space of a torus identified with $\{z \in \mathbb{C} \mid \Im z > 0\}$, which we define to be $\omega_{\mathbf{M}}(V)$. We define $\mathbf{M}[k]$ to be the complement of the tubes whose $\omega_{\mathbf{M}}$ have absolute value greater than or equal to k.

Since G_i is a Kleinian surface group, it also has a bi-Lipschitz model constructed by Minsky [29] and proved to be bi-Lipschitz in Brock-Canary-Minsky [10]. As was explained in Preliminaries, we ignore cusp neighbourhoods in the model manifolds of Minsky to make them models for the non-cuspidal parts. Let $\mathbf{M}_i$ be a model manifold for $(M_i)_0 = (\mathbb{H}^3/G_i)_0$ in the sense of Minsky with a bi-Lipschitz model map $f_i : \mathbf{M}_i \to (M_i)_0$. Minsky's construction is based on complete hierarchies of tight geodesics which are determined by the end invariants of M_i, as we briefly explained in Preliminaries. The model manifold has decomposition into blocks and Margulis tubes, which corresponds to a resolution of a complete hierarchy. When we talk about model manifolds $\mathbf{M}_i$, *we always assume the existence of complete hierarchies h_i beforehand*, and that the manifolds are decomposed into blocks and Margulis tubes using resolutions. The metric of model manifolds are defined as the union of metrics on internal blocks and metrics determined by conformal structures at infinity on boundary blocks. We should note that as was shown in [29], the decomposition of $\mathbf{M}_i$ into blocks and the metric on $\mathbf{M}_i$ depend only on h_i and end invariants, and are independent of choices of resolutions.

In the proof of Theorem A in [35] (§5.2), the following was also shown.

Proposition 4.3. *Let $x_i \in \mathbf{M}_i$ be a point in $\mathbf{M}_i$ such that $f_i(x_i)$ is within uniformly bounded distance from the basepoint y_i of M_i. Then $(\mathbf{M}_i[k], x_i)$ converges to $\mathbf{M}[k]$ for any $k \in [0, \infty)$ after passing to a subsequence. The model manifolds $\mathbf{M}$ and $\mathbf{M}_i$ have structures of labelled brick manifolds admitting block decompositions with the following condition. Let $\rho_i^{\mathbf{M}}$ be an approximate isometry between $\mathbf{M}_i[k]$ and $\mathbf{M}[k]$ corresponding to the geometric convergence. Then the following hold.*

1. *For any compact set K in $\mathbf{M}[k]$, the restriction $\rho_i \circ f_i \circ (\rho_i^{\mathbf{M}})^{-1}|K$ converges to $f|K$ uniformly as $i \to \infty$.*
2. *For any block b of $\mathbf{M}[k]$, its pull-back $(\rho_i^{\mathbf{M}})^{-1}(b)$ is a block in $\mathbf{M}_i[k]$ for large i.*
3. *For any brick B of $\mathbf{M}[k]$, its pull-back $(\rho_i^{\mathbf{M}})^{-1}(B)$ is contained in a brick of $\mathbf{M}_i[k]$ for large i.*
4. *We can arrange $\rho_i^{\mathbf{M}}$ so that it preserves the horizontal foliations.*

By defining a brick to be a maximal union of parallel horizontal leaves, we can define a brick decomposition of $\mathbf{M}_i[k]$. (Such a brick decomposition is called the *standard brick decomposition*.) A brick in $\mathbf{M}_i[k]$ in the condition (3) is one in this brick decomposition of $\mathbf{M}_i[k]$.

4.2. **Algebraic limits in the models.** Since the algebraic limit Γ of $\{G_i\}$ is contained in the geometric limit G_∞, there is an inclusion of $\pi_1(S)$ in $\pi_1(\mathbf{M})$ corresponding to the inclusion of Γ into G_∞. We realise this inclusion by a π_1-injective immersion $g : S \to \mathbf{M}$ so that $(f \circ g)_\# \pi_1(S)$ is equal to the image of $\pi_1(M')$ in $\pi_1(M_\infty)$ under the covering projection. We call such g an *algebraic locus*.

Lemma 4.4. *The immersion g can be homotoped to a map g' as follows.*

1. *The surface S is decomposed into incompressible subsurfaces $\Sigma_1, \ldots, \Sigma_m$, none of which is an annulus, and annuli $A_1, \ldots, A_n$.*
2. *The restriction of g' to Σ_j is a horizontal embedding into $\Sigma_j \times \{t_j\}$.*
3. *Each annulus $g'(A_j)$ is composed of $2n-1$ horizontal annuli and $2n$ vertical annuli for some $n \in \mathbb{N}$ and goes around a torus boundary of $\mathbf{M}$ n-times. See Figure 1.*

Proof. By the last condition in Theorem 4.2, we see that g is π_1-injective in $S \times [0,1]$. Since every π_1-injective map from S to $S \times [0,1]$ is homotopic to a horizontal surface, g is homotopic to a horizontal surface $S \times \{t\}$ in $S \times [0,1]$.

Since $\mathbf{M}$ is a brick manifold, we can homotope g within $\mathbf{M}$ so that $g(S)$ consists of horizontal leaves in bricks and vertical annuli. By the additivity of Euler characteristics, we see that the sum of the Euler characteristics of the horizontal leaves is equal to $\chi(S)$. We consider the projection of horizontal leaves to S. Since g is homotopic to $S \times \{t\}$ in $S \times I$, we see by the invariance of the algebraic intersection number that for each point $x \in S$ the surface $g(S)$ contains $x \times \{s\}$ for some $s \in I$. This implies that the horizontal leaves cannot overlap along a surface with negative Euler characteristic. It follows that only compact regions that $g(S)$ can bound in $S \times I$ are solid tori. If such a solid torus is contained in $\mathbf{M}$, we can eliminate it by a homotopy. Therefore the only remaining possibility is that each solid torus contains components of $\partial \mathbf{M}$. By the second condition of Theorem 4.2, there is only one boundary component contained in each solid torus. Thus the only possible situation is as in our statement. □

We call a map $g' : S \to \mathbf{M}$ as in Lemma 4.4 a *standard algebraic immersion*. Recall that there is a homotopy equivalence $\Phi_i : S \to M_i$ realising ϕ_i. By composing the inverse of the model map, we have a homotopy equivalence from S to $\mathbf{M}_i$, which *we denote by* $\Phi_i^{\mathbf{M}}$.

Lemma 4.5. *Let $\rho_i^{\mathbf{M}}$ be an approximate isometry between $\mathbf{M}_i[k]$ and $\mathbf{M}[k]$ with basepoints at the thick parts as in Proposition 4.3. For sufficiently large i, the immersion $(\rho_i^{\mathbf{M}})^{-1} \circ g'$ is homotopic to $\Phi_i^{\mathbf{M}}$ as a map to $\mathbf{M}_i$.*

Proof. By the definition of g', we see that $f \circ g'$ is homotopic to Ψ. Since $\rho_i^{-1} \circ \Psi$ is homotopic to Φ_i for large i, our lemma follows from the condition (1) of Proposition 4.3. □

Definition 4.6. Let e be a simply degenerate end of $\mathbf{M}$ contained in a brick $B = \Sigma \times J$. We say that e is *an upper algebraic end* if $J = [s, s')$ and $\Sigma \times \{s' - \epsilon\}$ is

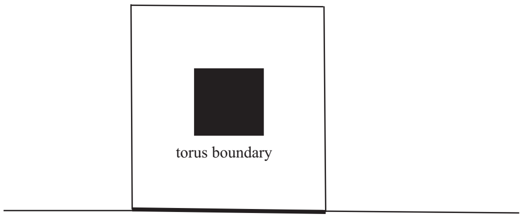

FIGURE 1. g' going around a torus boundary component (the case when $n = 1$).

freely homotopic to $g'(\Sigma)$ which lies in a horizontal part of $g'(S)$ in $\mathbf{M}$ for sufficiently small ϵ. In the same way, we say that e is *a lower algebraic end* if $J = (s, s']$ and $\Sigma \times \{s + \epsilon\}$ is freely homotopic to $g'(\Sigma)$ which lies in a horizontal part $g'(S)$ for sufficiently small ϵ.

Similarly, a core curve of an open annulus boundary component or a longitude (i.e. a horizontal curve) of a torus boundary component of $\mathbf{M}$ is said to be an *algebraic parabolic curve* if it is homotopic to a simple closed curve lying on a horizontal part of $g'(S)$. We also call its image of the vertical projection to S an algebraic parabolic curve. A parabolic curve is said to be upper or lower in the same way as simply degenerate ends, but we should note if it lies on a torus boundary component around which $g'(S)$ goes, then the curve is defined to be both upper and lower at the same time. An algebraic parabolic curve is said to be *isolated* if it corresponds to an isolated parabolic locus of M'.

Lemma 4.7. *Any algebraic parabolic curve lying on a torus boundary component of* $\mathbf{M}$ *is isolated.*

Proof. Let c be an algebraic parabolic curve lying on a torus boundary component of $\mathbf{M}$. Let P be a parabolic locus of a relative core C of $(M')_0$ into which the lift of $f(c)$ to M' is homotopic. Suppose, seeking a contradiction, that P is not isolated. Then, there is a simply degenerate end e touching the $\mathbb{Z}$-cusp corresponding to P. By the Thurston's covering theorem (see [38] and Canary [14]), there is a neighbourhood U of e which is projected in to M_∞ homeomorphically by the covering projection. This implies that $\mathbf{M}$ has a simply degenerate brick which touches an open annulus boundary of $\mathbf{M}$ into which c is homotopic. Since no two boundary components of $\mathbf{M}$ have homotopic essential closed curves, this contradicts the assumption that c lies on a torus boundary. □

Lemma 4.8. *The algebraic simply degenerate ends of* $\mathbf{M}$ *ends correspond one-to-one to the simply degenerate ends of* M'_0 *by mapping them by* f *and lifting them to* M'_0. *The upper (resp. lower) ends correspond to upper (resp. lower) ends of* M'_0.

Proof. Consider a simply degenerate end corresponding to the upper ideal front of a brick $B = \Sigma \times [s, s')$ of $\mathbf{M}$. By the definition of the model map f, for each simply degenerate end of $\mathbf{M}$, there is an infinite sequence of horizontal surfaces $\Sigma \times \{t_j\}$ in B' tending to $\Sigma \times \{s'\}$ which are mapped to a sequence of pleated surfaces $f(\Sigma \times \{t_j\})$ tending to the corresponding simply degenerate end e of $(M_\infty)_0$. Since $\Sigma \times \{t\} \in B'$ is freely homotopic into $g'(S)$, the pleated surfaces $f(\Sigma \times \{t_j\})$ lift to pleated surfaces $\tilde{f}_i$ tending to an end of M'_0.

Since the model map f has degree 1 with respect to the orientation of $(M_\infty)_0$, the end e is situated above $f \circ g'(S)$. Lifting this to M_0', we see that the end to which the $\tilde{f}_i$ tend is an upper end. Similarly, we can show that if the simply degenerate brick B has the form $\Sigma \times (s, s']$, then the corresponding end of M_0' is a lower end.

Conversely, suppose that e' is a simply degenerate end of M_0'. By Thurston's covering theorem (see Thurston [38] and Canary [14]), there is a neighbourhood E of e' such that $p|E$ is a proper embedding into $(M_\infty)_0$. Let $\bar{e}$ denote the simply degenerate end of $(M_\infty)_0$ contained in $p(E)$. Then, there is a simply degenerate $\hat{e}$ of $\mathbf{M}$ which is sent to $\bar{e}$ by f. Since e' is simply degenerate, there is an essential subsurface Σ of S and a sequence of pleated surfaces $h_i : \Sigma \to M_0'$ taking $\partial\Sigma$ to $\partial M_0'$ which tend to e'. Their projections $p \circ h_i$ are pleated surfaces tending to $\bar{e}$. This implies that the end $\hat{e}$ is contained in a simply degenerate brick $B_e \cong \Sigma \times J$, where J is a half-open interval. Since $f(\Sigma \times \{t\})$ is homotopic to $p \circ h_i$ and $p \circ h_i$ is homotopic into $f \circ g'(S)$, we see that $\Sigma \times \{t\}$ is freely homotopic to $g'(\Sigma)$. By Lemma 4.4, this is possible only when $\Sigma \times \{t\}$ is homotopic into a horizontal part of $g'(S)$, and we see that the end $\hat{e}$ is algebraic. □

As was shown in [35], except for the geometrically finite ends lying on $S \times \{0, 1\}$, all the tame ends of $\mathbf{M}$ are simply degenerate. Next we shall see how simply degenerate ends in the model manifold $\mathbf{M}$ are approximated in $\mathbf{M}_i$. Recall that the model manifold $\mathbf{M}_i$ corresponds to a hierarchy h_i of tight geodesics. Recall also that we have a homeomorphism $\hat{\Phi}_i : S \times (0, 1) \to M_i$ inducing ϕ_i between the fundamental groups. This determines an embedding ι of the standard $S \times (0, 1)$ into $S \times [0, 1]$ in which $\mathbf{M}_i$ is embedded. We identify the standard $S \times [0, 1]$ and $S \times [0, 1]$ in which $\mathbf{M}_i$ is embedded so that this ι becomes an inclusion. In other words, by this identification, the model map f_i is homotopic to $\hat{\Phi}_i$ if restricted to $S \times (0, 1)$. We identify two $S \times [0, 1]$ in which $\mathbf{M}_{i_1}$ and $\mathbf{M}_{i_2}$ are embedded respectively for every pair i_1, i_2 using $\hat{\Phi}_{i_1}$ and $\hat{\Phi}_{i_2}$. We also identify the standard $S \times [0, 1]$ with $S \times [0, 1]$ in which $\mathbf{M}$ is embedded so that in $S \times J$ appearing in (6) of Theorem 4.2, the map $f_\#$ is the same as ψ.

We fix a complete marking μ on S. For a domain X in S, by considering a component of $\mu|X$, we can define a basepoint in $\mathcal{CC}(X)$. We call this basepoint the *basepoint determined by marking*.

Proposition 4.9. *Let $B = \Sigma \times I$ be a simply degenerate brick in $\mathbf{M}$ whose end e is algebraic. Then there is a geodesic γ_i contained in the hierarchy h_i as follows.*

1. *The support of γ_i is $\mathrm{Int}\Sigma$.*
2. *After passing to a subsequence, either all γ_i are geodesic rays, or they are finite geodesics and the length of γ_i goes to ∞ as $i \to \infty$.*
3. *In the case when the γ_i are geodesic rays, their endpoints at infinity converge to the ending lamination of e in $\mathcal{EL}(\mathrm{Int}\Sigma)$.*
4. *Suppose that the γ_i are finite geodesics. In the case when the end e is upper, the last vertex of γ_i converges to the ending lamination of e, whereas the first vertices stay in a bounded distance from a basepoint in $\mathcal{CC}(\mathrm{Int}\Sigma)$ determined by marking. In the case when the end is lower, the first vertex of γ_i converges to the ending lamination whereas the last vertices stay in a bounded distance from the basepoint determined by marking.*

4.3. **Proof of Proposition 4.9.**

Let $\mathcal{T}$ be the union of all boundary components of $\mathbf{M}$ that meet the vertical boundary of B. The preimage by $\rho_i^{\mathbf{M}}$ of each component of $\mathcal{T}$ lies on the boundary of either a Margulis tube or a $\mathbb{Z}$-cusp neighbourhood of $\mathbf{M}_i$. For sufficiently large i, we consider the union $\mathbf{V}_i$ of all Margulis tubes and cusp neighbourhoods whose intersection with $B_{r_i}(\mathbf{M}_i, x_i)$ are mapped by $\rho_i^{\mathbf{M}}$ into $\mathcal{T}$. Let $\mathbf{B}(i)$ be a maximal subset of the form $\Sigma \times J$ with $J \subset I$ which lies in the component of $B \cap B_{K_i r_i}(\mathbf{M}, x_\infty)$ containing x_∞.

Let $\hat{\mathbf{M}}_i$ be the complement of $\mathrm{Int}\mathbf{V}_i$ in $\mathbf{M}_i$. Regarding $\mathbf{M}_i$ as embedded in $S\times[0,1]$, we can decompose $\hat{\mathbf{M}}_i$ into bricks by defining a brick to be a maximal union of parallel horizontal leaves, i.e. by considering a standard brick decomposition. Since all horizontal leaves in B are parallel in $\mathbf{M}$ and $\rho_i^{\mathbf{M}}$ preserves the horizontal foliation, we see that $(\rho_i^{\mathbf{M}})^{-1}(\mathbf{B}(i))$ is contained in a brick $B_i = \Sigma_i \times J_i$ in $\hat{\mathbf{M}}_i$. Since the end e in B is algebraic, $\Sigma \times \{t\}$ in B is homotopic to $g'(\Sigma)$ in $\mathbf{M}$. Pulling this back to $\mathbf{M}_i$, we see that Σ_i is homotopic to $\Phi_i^{\mathbf{M}}(\Sigma)$. By our way of identifying the $S \times [0,1]$ in which the $\mathbf{M}_i$ lie, we can regard Σ_i as being equal to Σ.

The length of the core curve of every tube in $\mathbf{V}_i$ goes to 0 as $i \to \infty$. Therefore, by the short curve theorem of Minsky [29], every such core curve is vertically homotopic to a vertex appearing in h_i. This shows that the tube union for $\mathbf{M}_i$ induces that of $\hat{\mathbf{M}}_i$.

We shall now review the notion of tube unions corresponding to h_i introduced in §3.3 of [35].

Definition 4.10. Let g be a tight geodesic contained in the hierarchy h_i with $\xi(D(g)) > 4$. Corresponding to g, we have a sequence $\mathcal{V}_g$ of disjoint unions of tubes called tube simplices, which is either a finite sequence $\{V_1^g, \dots V_k^g\}$ or infinite sequence of the forms $\{V_1^g, \dots\}$ or $\{\dots, V_{-1}^g\}$ embedded in $D(g) \times J$ in $\mathbf{M}_i$ with the following properties. We use the symbol $\sup V_j^g$ and $\inf V_j^g$, in the same way as for bricks.

(i) $\overline{D}(g) \times J$ is a brick with respect to the standard brick decomposition of the complement of tubes $\mathcal{V}_{g'}$ for all g' in h_i to which g is subordinate.
(ii) Each tube simplex V_j^g is a union of disjoint solid tori each of which is bounded by two horizontal annuli and two vertical annuli.
(iii) The lower horizontal boundaries of the components of V_j^g lie on the same horizontal leaf, and so do the upper horizontal boundaries. (Therefore $\inf V_j^g$ and $\sup V_j^g$ are well defined.)
(iv) The core curves of the tube simplex V_j^g are taken to the j-th simplex of γ_i by the vertical projection $p : S \times [0,1] \to S$. (We shall say that the core curve is vertically homotopic to the j-th simplex in this situation.) In particular, the first and last tube simplices are connected, i.e. solid tori.
(v) We have $\inf V_{j+1}^g = \sup V_j^g$.
(vi) The lower front of the first tube lies on $D(g) \times \inf J$, and the upper front of the last tube lies on $D(g) \times \sup J$. Unless g is the main geodesic of h_i, the first tube is attached along its lower front to a component of a tube simplex corresponding to a simplex u on g_1 with $(g_1, u) \overset{d}{\swarrow} g$, and the last tube is attached along its upper front to a component of a tube simplex corresponding to a simplex w on g_2 with $g \overset{d}{\searrow} (g_2, w)$.
(vii) The core curves of $\mathcal{V}_{g_1} \cap (D(g) \times \inf J)$ are vertically homotopic to $I(g)$, and those of $\mathcal{V}_{g_2} \cap (D(g) \times \sup J)$ are vertically homotopic to $T(g)$ for g_1, g_2 as above.

Definition 4.11. In the case when $\xi(D(g)) = 4$, the properties (ii)-(v) should be modified as follows whereas the conditions (i), (vi) and (vii) remain the same.

- (ii*) Each V_j^g is a solid torus bounded by two horizontal annuli and two vertical annuli.
- (iii*) The core curve of V_j^g is vertically homotopic to the j-th vertex of g.
- (iv*) We have $\inf V_{j+1}^g > \sup V_j^g$.
- (v*) There is no tube V in a tube union $\mathcal{V}_{g'}$ with $g' \in h_i$ such that either $\inf V$ or $\sup V$ lies in the open interval $(\sup V_j^g, \inf V_{j+1}^g)$.

In [35], there was an operation to connect two homotopic solid tori appearing in the process of putting tube unions. We regard this operation as putting a tube union corresponding to a geodesic of length 0 in the present argument. Therefore, the decomposition into blocks is obtained just by putting tube unions.

We call the union of tubes in $\mathcal{V}_g$ the *tube union* corresponding to g. Now we consider to put tube unions corresponding to geodesics of h_i, one by one starting from the main geodesic. We assume that when we put a tube union corresponding to a geodesic g, all the tube unions corresponding to the geodesics to which g is subordinate have already been put in $\mathbf{M}$. We define $\mathcal{V}(h_i)$ to be $\cup_{g\in h_i}\mathcal{V}_g$, and $\mathcal{V}_i$ to be the union of all the tubes in $\mathcal{V}(h_i)$. The complement $\mathcal{V}_i$ in $\mathbf{M}_i$ is the brick manifold $\mathbf{M}_i[0]$. For a tube simplex V in $\mathcal{V}(h_i)$, we denote by $\hat{V}$ the union of V and the tubes to which V is attached and which existed before V is put. By the condition (v*) above, for any brick $D(g) \times J$ appearing in the construction of $\mathcal{V}_g$, its real front F intersects $\mathcal{V}_i$ in such a way that every component of $F \setminus \mathcal{V}_i$ is a thrice-punctured sphere.

We shall show that the intersection of the tube unions in $\mathcal{V}(h_i)$ and B_i gives a hierarchy of tight geodesics in Σ. For that, we shall first show that each tube union intersecting B_i defines a tight geodesic on a subsurface of Σ. First, we consider the case when a tube union penetrates B_i in the following sense. We say that a tube union $\mathcal{V}_g$ *penetrates* B_i if one of the following conditions is satisfied.

- (a) There is a non-empty consecutive sequence $\{V_{j_0}^g, \dots, V_{j_1}^g\}$ in $\mathcal{V}_g$ such that $\inf B_i \leq \inf V_{j_0}^g$, $\sup V_{j_1}^g \leq \sup B_i$ whereas $\inf \hat{V}_{j_0-1}^g < \inf B_i$ and $\sup \hat{V}_{j_1+1}^g > \sup B_i$ and at least one of $V_{j_0-1}^g, V_{j_0}^g, \dots, V_{j_1+1}^g$ intersects $\mathrm{Int}B_i$. (Note that putting $\hat{}$ is necessary only when V_{j_0-1} or V_{j_1+1} is the first or last tube of $\mathcal{V}_g$.)
- (b) There is a consecutive pair of tube simplices V and V' in $\mathcal{V}_g$ both intersecting B_i such that $\inf \hat{V} < \inf B_i \leq \sup V$, $\inf V'' \leq \sup B_i < \sup \hat{V}'$.
- (c) There is a tube simplex V in $\mathcal{V}_g$ with $V \cap B_i \neq \emptyset$ and $\inf \hat{V} < \inf B_i, \sup \hat{V} > \sup B_i$.
- (d) The brick B_i has an upper simply degenerate end. The geodesic g is a ray, and there is a consecutive sequence $\{V_{j_0-1}^g, V_{j_0}^g, \dots\}$ in $\mathcal{V}_g$ one of which intersects B_i such that $\inf \hat{V}_{j_0-1}^g < \inf B_i$ and $\inf B_i \leq \inf V_{j_0}^g$.
- (e) The brick B_i has a lower simply degenerate end. The geodesic g is a ray in the negative direction, and there is a consecutive sequence $\{\dots, V_{j_1}^g, V_{j_1+1}^g\}$ in $\mathcal{V}_g$ one of which intersects B_i such that $\sup \hat{V}_{j_1+1}^g > \sup B_i$ and $\sup B_i \geq \sup V_{j_1}^g$.

The subsequences of $\mathcal{V}_g$ appearing the conditions (a)-(e) are called *penetrating subsequence*. See Figure 2.

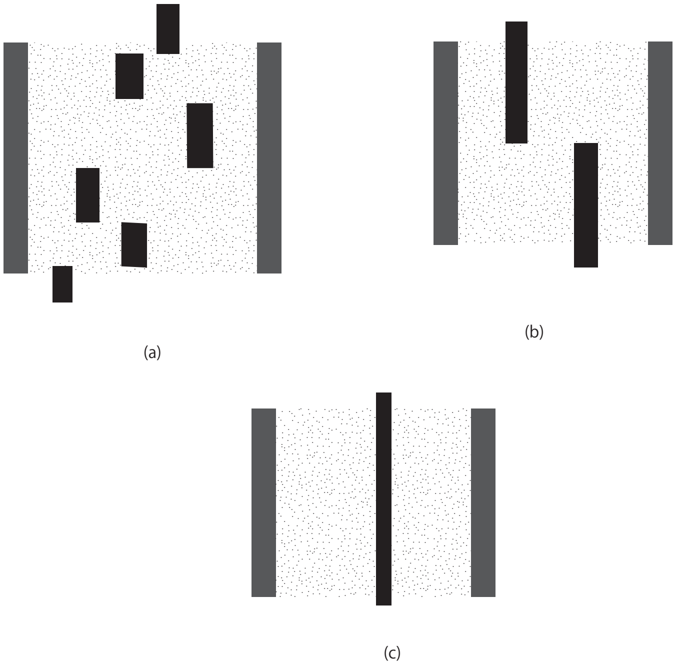

Figure 2. Tube unions penetrating B_i.

Lemma 4.12. *Let $\mathcal{V}_g$ be a tube union for $g \in h_i$ which penetrates B_i. Then the core curves of the tubes in $\mathcal{V}_g$ are vertically homotopic to simplices in a tight sequence supported on a domain contained in S in such a way that the core curves of the j-th tube union are homotopic to the j-th simplex. Moreover, in the cases (a), (d) and (e), the domain $D(g)$ is contained in Σ.*

Proof. This is obvious in the cases of (b) and (c). We now consider the case (a). By the condition of the case (a), there are at least three consecutive tube simplices $V^g_j, V^g_{j+1}, V^g_{j+2}$ in $V^g_{j_0-1}, \dots, V^g_{j_1+1}$. We let c^g_j, c^g_{j+1} and c^g_{j+2} be the simplices vertically homotopic to their core curves. Since g is a tight geodesic, $c^g_j \cup c^g_{j+2}$ fills up $D(g) \setminus c^g_{j+1}$. If $D(g)$ is not a subsurface of either Σ or $S \setminus \Sigma$, then there is a component γ of $\mathrm{Fr}\Sigma$ contained in $D(g)$. On the other hand, the curve $\gamma \subset D(g)$ is disjoint from all of the three simplices c^g_j, c^g_{j+1} and c^g_{j+2} since the tubes V^g_j, V^g_{j+1} and V^g_{j+2} are disjoint from $\mathbf{V}_i$. This is a contradiction. Also, since at least one of $V^g_{j_0-1}, V^g_{j_0}, \dots, V^g_{j_1+1}$ intersects B_i by assumption, we see that $D(g)$ cannot be contained in $S \setminus \Sigma$. Therefore, $D(g)$ is a subsurface of Σ, and the core curves of $V^g_{j_0-1}, \dots, V^g_{j_1+1}$ constitute a tight sequence supported on a domain in Σ. We also note that this implies that all of $V^g_{j_0-1}, \dots, V^g_{j_1+1}$ intersect B_i and $V^g_{j_0}, \dots, V^g_{j_1}$ are contained in B_i. We can argue in the same way in the cases (d) and (e), and conclude that $D(g)$ is a domain in Σ also in these cases and that the core curves of $V^g_{j_0-1}, \dots$ or $\dots, V^g_{j_1+1}$ constitute a tight geodesic ray supported there. $\square$

We should note the following. Suppose that g penetrates B_i and that $D(g)$ is an essential subsurface of $\mathrm{Int}\Sigma$. Let c be a component of $\mathrm{Fr}_\Sigma D(g)$. Since $\mathcal{V}_g$ lies in $D(g) \times J$, we see that there is a tube V_c in $\mathcal{V}_i$ whose core curve is vertically homotopic to c and it penetrates B_i as in the case (c) above. Note that V_c may be a union of tubes corresponding to vertices lying on several different geodesics. The tube $V_c \cap B_i$ must be already put into $\mathbf{M}_i$ when we start to put $\mathcal{V}_g$.

Secondly, we consider tube unions which do not penetrate B_i but stop inside B_i. A tube union $\mathcal{V}_g$ is said to *stop inside* B_i when one of the following holds.

(a*) There is a consecutive sequence $\{V^g_{j_0-1}, \dots, V^g_k\}$ in $\mathcal{V}_g$ ending at the last tube of $\mathcal{V}_g$, at least one of which intersects B_i and such that $\inf V^g_{j_0-1} < \inf B_i$, $\inf V^g_{j_0} \geq \inf B_i$, whereas $\sup \hat{V}^g_k \leq \sup B_i$. When $k = 2$, we need to assume that both $V^g_{j_0}$ and V^g_k intersect B_i.

(b*) There is a consecutive sequence $\{V^g_1, \dots, V^g_{j_1+1}\}$ of $\mathcal{V}_g$ starting at the first tube of $\mathcal{V}_g$, at least one of which intersects B_i and such that $\sup V^g_{j_1+1} > \sup B_i$, $\sup V^g_{j_1} \leq \sup B_i$, whereas $\inf \hat{V}^g_1 \geq \inf B_i$. When $k = 2$, we need to assume that both V^g_1 and V^g_2 intersect B_i.

(c*) The last tube V^g_k in $\mathcal{V}_g$ intersects B_i and $\inf V^g_k < \inf B_i$ and $\sup \hat{V}^g_k \leq \sup B_i$.

(d*) The first tube V^g_1 of $\mathcal{V}_g$ intersects B_i and $\inf \hat{V}^g_1 \geq \inf B_i$ and $\sup V^g_1 > \sup B_i$.

By the same argument as Lemma 4.12, we can show the following.

Lemma 4.13. *Let $\mathcal{V}_g$ be a tube union for $g \in h_i$ which stops inside B_i. Then the core curves of the tubes in $\mathcal{V}_g$ are vertically homotopic to a tight sequence supported on a subsurface of S. Moreover, in the cases (a*) and (b*) with $k > 2$, the domain $D(g)$ is contained in Σ.*

Thirdly, we consider the case when a tube union is totally contained in B_i. We say a tube union $\mathcal{V}_g$ is *totally contained* in B_i when one of the following conditions holds.

(a**) For $\mathcal{V}_g = \{V^g_1, \dots, V^g_k\}$, at least one of the tubes intersects B_i and it holds that $\inf B_i \leq \inf V^g_1$ and $\sup V^g_k \leq \sup B_i$. When $k = 2$, we need to assume that both of the tubes V^g_1, V^g_2 intersect B_i.

(b**) For an infinite sequence $\mathcal{V}_g = \{V^g_1, \dots\}$ or $\mathcal{V}_g = \{\dots V^g_{-1}\}$ at least one of whose entries intersects B_i, it holds $\inf B_i \leq \inf V^g_j$ and $\sup V^g_j \leq \sup B_i$ for all j.

Again by the same argument as Lemma 4.12, we have the following.

Lemma 4.14. *Let $\mathcal{V}_g$ be a tube union for $g \in h_i$ which is totally contained in B_i. Then the core curves of the tubes in $\mathcal{V}_g$ are vertically homotopic to a tight sequence supported on a subsurface of S. Moreover except for the case (a**) with $k = 2$, the domain $D(g)$ is contained in Σ.*

We should note that, by our definitions above, if a tube union has a tube intersecting $\mathrm{Int}B_i$, then it either penetrates or stops inside or is totally contained in B_i except for the case when $k = 2$ and one of the tube simplices stays outside B_i. In this latter case, we can ignore the effect of putting the tube union in B_i since it does not affect the construction of hierarchies in the following argument. As a convention, when we say that a tube union intersects $\mathrm{Int}B_i$, we always *assume that it either penetrates or stops inside or is totally contained in B_i.*

Now, we shall show that the geodesics on $\mathrm{Int}\Sigma$ which $\mathcal{V}_g (g \in h_i)$ gives as above has a structure of a hierarchy. Suppose that $\mathcal{V}_g$ either penetrates or stops inside or is totally contained in B_i. Let γ^g a tight sequence supported on a subsurface of Σ induced by $\mathcal{V}_g$ as shown in Lemmata 4.12-4.14. We define $D(\gamma^g)$ to be $D(g)$

except for the cases (b), (c) for the penetrating sequences and the case when $k \leq 2$ for the sequences either stopping inside or totally contained in B_i. In these latter cases, we define $D(\gamma^g)$ to be $D(g) \cap \Sigma$. By this, we always have $D(\gamma^g) \subset \Sigma$. We define $I(B_i)$ to be the core curves of $\mathcal{V}_i$ intersecting the upper front of B_i projected vertically to $D(\gamma^g)$ if the front is real, with empty transversals, and similarly define the terminal marking $T(B_i)$.

Lemma 4.15. *Let g be a tight geodesic in h_i with $\xi(D(h_i)) \geq 4$ such that $\mathcal{V}_g$ intersects $\mathrm{Int}B_i$. If $\mathcal{V}_g$ is the first tube union in the above construction that intersects $\mathrm{Int}B_i$, then $\mathcal{V}_g$ must penetrate B_i and $D(\gamma^g) = \mathrm{Int}\Sigma$. Moreover, in the cases (a) and (d), the tube $V^g_{j_0-1}$ is the first tube of $\mathcal{V}_g$, and in the cases (a) and (e), the tube $V^g_{j_1+1}$ is the last tube of $\mathcal{V}_g$. The sequence γ^g becomes a tight geodesic by defining its initial marking to be $I(B_i)$ and its terminal marking to be $T(B_i)$ if the lower and/or upper ends are real. If one of the fronts of B_i is ideal, then we define the endpoint of γ^g at infinity to be the initial or terminal marking.*

If $\mathcal{V}_g$ is not the first tube union intersecting B_i, then the support of $\mathcal{V}_g$ is an essential subsurface of Σ, and there are geodesics g_1, g_2 in h_i and simplices w_1, w_2 on them such that $(\gamma^{g_1}, w_1) \overset{d}{\swarrow} \gamma^g \overset{d}{\searrow} (\gamma^{g_2}, w_2)$. We let $I(\gamma^g)$ be $I(D(\gamma^g), \gamma^{g_1})$ unless w_1 is the first vertex and $I(B_i)|D(\gamma^g)$ if it is. Similarly, we let $T(\gamma^g)$ be $T(D(\gamma^g), \gamma^{g_2})$ unless w_2 is the last vertex, and $T(B_i)|D(\gamma^g)$ if it is..

The family $\{\gamma^g \mid g \in h_i\}$ constitutes a 4-complete generalised hierarchy on $\mathrm{Int}\Sigma$.

Proof. Suppose that $\mathcal{V}_g$ is the first tube union intersecting $\mathrm{Int}B_i$. Let $h_i(g)$ be the subfamily of h_i consisting of the geodesics to which g is subordinate, $\mathcal{V}_{h_i(g)}$ the union of all $\mathcal{V}_{g'}$ with $g' \in h_i(g)$, and $\mathbf{V}_{h_i(g)}$ the union of all the tubes contained in $\mathcal{V}_{h_i(g)}$. Since no tubes in $\mathcal{V}_{h_i(g)}$ can intersect $\mathrm{Int}B_i$, the first and last tube simplices of $\mathcal{V}_g$ that intersect $\mathrm{Int}B_i$ (provided that they exist) must intersect the fronts of B_i. In the first or the last tube simplex does not exit, then $\mathcal{V}_g$ consists of infinite tubes and it satisfies the condition (d) or (e). In either case, we see that $\mathcal{V}_g$ penetrates B_i.

Now suppose that we are in the situation of (a). Recall that by the definition of tube unions, $\overline{D}(g) \times J$ is a brick with respect to the standard brick decomposition of $\mathbf{M}_i \setminus \mathrm{Int}\mathbf{V}_{h_i(g)}$, and that the first and last tubes of $\mathcal{V}_g$ are attached to tubes in $\mathcal{V}_{h_i(g)}$ along their fronts. In particular, $\mathcal{V}_{h_i(g)}$ contains tubes with core curves whose union is vertically homotopic to $\mathrm{Fr}D(g)$. We let $\mathcal{V}(\mathrm{Fr}D(g))$ be the family consisting of these tubes. Since $D(g) \times J$ intersects $\mathrm{Int}B_i$ and $D(g)$ is contained in Σ, every tube of $\mathcal{V}(\mathrm{Fr}D(g))$ either intersects $\mathrm{Int}B_i$ or touches the vertical boundary of B_i. Since we assumed that $\mathcal{V}_g$ is the first tube union intersecting $\mathrm{Int}B_i$, there can be no tube in $\mathcal{V}(\mathrm{Fr}D(g))$ intersecting B_i. Therefore, every tube in $\mathcal{V}(\mathrm{Fr}D(g))$ touches the vertical boundary of B_i, and we have $D(g) = \mathrm{Int}\Sigma$. This also implies that the tubes in $\mathcal{V}(\mathrm{Fr}D(g))$ are contained in $V_{h_i(g)}$, and that the first and last tubes in $\mathcal{V}_g$ intersect $\mathrm{Int}B_i$. Even in the cases (b) and (c), the same argument implies that $D(\gamma^g) = \Sigma$. We can also deal with the case when γ^g is infinite in the same way.

Next suppose that $\mathcal{V}_g$ is not the first tube union intersecting $\mathrm{Int}B_i$. Such a tube union exists only when $\xi(\Sigma) > 4$. Then there is $g_0 \in h_i(g)$ such that $\mathcal{V}_{g_0}$ is the first tube union intersecting $\mathrm{Int}B_i$. As was shown above, $\mathcal{V}_{g_0}$ penetrates B_i. It follows that every horizontal leaf of B_i must intersect a tube in $\mathcal{V}_{g_0}$. Therefore, there can be no $\Sigma \times J$ in $\mathbf{M}_i \setminus \mathrm{Int}\mathbf{V}(h_i(g))$ touching $\mathrm{Int}B_i$. This shows that the support of γ^g must be an essential subsurface of Σ.

Suppose that $\mathcal{V}_g$ penetrates B_i. By our construction of tube unions, the tubes in $\mathcal{V}_g$ are put in $D(g) \times J$ in the complement of $\mathbf{M}_i \setminus \mathrm{Int}\mathbf{V}_{h_i(g)}$ which is a brick of the standard brick decomposition of $\mathbf{M}_i \setminus \mathrm{Int}\mathbf{V}_{h_i(g)}$. This means that there is a tube union V_{i_0} corresponding to a simplex v_{i_0} of a geodesic g' in $h_i(g)$ such that $\mathrm{Fr}D(g) \times J$ lies on the vertical boundary of V_{i_0}. We need to show $(g', v_{i_0}) \overset{d}{\swarrow} g \overset{d}{\searrow} (g', v_{i_0})$. If v_{i_0} is neither first nor the last vertex of γ', then $\hat{V}_{i_0-1}$ and $\hat{V}_{i_0+1}$, corresponding the predecessor and the successor of v_{i_0}, must intersect the the fronts of B_i. In this case, $\mathrm{prec}(v_{i_0}) \cap \mathrm{Int}\Sigma$ is the first vertex of $\gamma^{g'}$ and $\mathrm{succ}(v_{i_0}) \cap \mathrm{Int}\Sigma$ is the last vertex of $\gamma^{g'}$, and we have $(g', v_{i_0}) \overset{d}{\swarrow} g \overset{d}{\searrow} (g', v_{i_0})$. If v_{i_0} is the first vertex of $\gamma^{g'}$, then $\hat{V}_{i_0}$ intersects the lower front of B_i. In this case, by our assumption, $I(\gamma^{g'})$ is equal to $I(B_i)|D(g')$, and we have $(g', v_{i_0}) \overset{d}{\swarrow} g$ again. Similarly, we have $g \overset{d}{\searrow} (g', v_{i_0})$ even when v_{i_0} is the last vertex of $\gamma^{g'}$.

Next we consider the case when g stops inside B_i. Then for either the first or last tube V of $\mathcal{V}_g$, the tube $\hat{V}$ is contained in B_i. We shall only consider the case when V is the last tube. The case when V is the first tube can be dealt with in the same way just turning everything upside down.

Let $W_1, \dots, W_p$ be tubes in $\mathbf{V}(h_i(g))$ intersecting $\mathrm{Fr}D(g) \times J$, and let g^* be a geodesic in $h_i(g)$ such that $\mathcal{V}_{g^*}$ contains a tube contained in one of $W_1, \dots, W_p$ which appears or is prolonged within $\Sigma \times [\inf B_i, \sup J]$ latest. Since g^* lies in $h_i 9g0$, we have $D(g) \subset D(g^*)$. Let v be a simplex of g^* giving this tube in $W_1, \dots, W_p$. The tube union $\mathcal{V}_{g^*}$ was put into $D(g^*) \times J^*$ which is a brick in the standard brick decomposition of $\mathbf{M}_i \setminus \mathrm{Int}\mathbf{V}(h_i(g^*))$. Since $\inf J^* < \sup J$ by our definition of g^*, we see that $D(g) \times J$ is contained in $(D(g^*) \setminus v) \times J^*$. Therefore we see that $D(g)$ is a component domain of v. The last tube V of $\mathcal{V}_g$ is attached along its upper front to a tube V' which is a component of $\mathbf{V}(h_i(g))$. Let $X_1, \dots, X_q$ be tubes in $\mathbf{V}(h_i(g))$ whose core curves are vertically projected into $D(g)$ such that $\inf X_1 = \cdots = \inf X_q = \inf V'$. If v is not the last vertex of g^*, then $\sup J^* > \sup J$, and there is a tube corresponding to $\mathrm{succ}(v)$. Since $D(g^*) \supset D(g)$, the tubes $X_1, \dots, X_q$ cannot be those which already existed at the time when we put $\mathcal{V}_{g^*}$. Therefore $\mathrm{succ}(v)$ contains curves vertically homotopic to the core curves of $X_1, \dots X_q$. By setting $T(\gamma^g)$ to be $\mathrm{succ}(v)|D(g)$, we have $\gamma^g \overset{d}{\searrow} \gamma^{g^*}$ at v then. If v is the last vertex, then $T(g^*)$ must contain curves vertically homotopic to the core curves of $X_1, \dots, X_1$ by the condition (vii) in the definition of tube unions. By setting $T(\gamma^g)$ to be $T(g^*)|D(\gamma^g)$, we have $\gamma^g \overset{d}{\searrow} \gamma^{g^*}$ at v.

We can show that $\gamma^g = g$ is subordinate to some γ^{g_1} and γ^{g_2} with $g_1, g_2 \in h_i(g)$ in the same way even when g is totally contained in B_i just by repeating the argument above at both $\sup J$ and $\inf J$.

The 4-completeness of $\{\gamma^g\}$ follows immediately from the completeness of h_i. □

Let $h(B_i)$ denote the 4-complete generalised hierarchy $\{\gamma^g\}$ in the above lemma.

Now we return to the proof of Proposition 4.9. We shall next show that the main geodesic of $h(B_i)$ gets longer and longer whereas the lengths of other geodesics which are located near the basepoint have bounded lengths.

Lemma 4.16. *The length of the main geodesic $g_{h(B_i)}$ goes to ∞ as $i \to \infty$.*

Proof. By our assumption, the end contained in B is algebraic. We can assume, as before, that the end is upper without loss of generality, for the case when it is lower can be dealt with just turing everything upside down.

Consider a resolution $R_i = \{\tau^i_j\}$ of the generalised hierarchy $h_i(B_i)$, where each τ^i_j denotes a slice in $h_i(B_i)$. Since B is simply degenerate, by our definition of $h_i(B_i)$, the number of slices in R_i goes to ∞ as $i \to \infty$. Recall, as was shown in Minsky [29], that each slice corresponds to a split level surface in B_i. Note that each component of a split level surface is a thrice-punctured sphere whose isometry type is unique. Let D be its diameter. We define D_S to be $(\xi(S) - 2)D$, and let E be the diameter of interior blocks, which are all isometric. Take a point w_∞ in B outside the Margulis tubes so that the distance modulo the Margulis tubes between w_∞ and the front of B is greater than the constant $2(E + D_S)$, and let w_i be $(\rho^{\mathbf{M}}_i)^{-1}(w_\infty)$, which is contained in B_i. Let b_i be a block of B_i containing w_i. We say that a slice contains the block b_i if the corresponding split level surface passes through b_i. By the definition of resolution, the subset of slices in R_i consisting of those containing b_i is a consecutive sequence. Let $R(b_i)$ denote this subsequence of R_i. We shall first show the following.

Claim 4.17. The number of slices in $R(b_i)$ is bounded independently of i.

Proof. Suppose, seeking a contradiction, that the number of slices in $R(b_i)$ is unbounded as $i \to \infty$. Then, there must be a geodesic $g_i \in h_i(B_i)$ such that the number of distinct pairs which appear in slices in $R(b_i)$ and whose first entries are g_i goes to ∞ as $i \to \infty$. Since all of the slices in $R(b_i)$ contain b_i, the geodesic g_i cannot be the main geodesic of $h_i(B_i)$. Let c_i be a frontier component of $D(g_i)$ in Σ, and let V_i denote the Margulis tube in $\mathbf{M}_i$ whose core curve is vertically homotopic to c_i. As was shown in §9 of Minsky [29], we see that $\Im\omega_{\mathbf{M}_i}(V_i)$ goes to ∞ as $i \to \infty$. Pick up a slice σ_i of $R(b_i)$ containing a pair with its first entry g_i, and consider the corresponding split level surface $f_i : \Sigma \to B_i$. The Margulis tubes which f_i touches give rise to a pants decomposition t_i of Σ. Since there are only finitely many ways to decompose a surface into pairs of pants up to homeomorphisms, by taking a subsequence, we can assume that there is a homeomorphism $k_i : \Sigma \to \Sigma$ such that the pants decomposition of Σ induced from t_i by pulling it back by k_i to Σ is independent of i. We denote by $\mathcal{K}$ the collection of simple closed curves giving this decomposition on Σ.

We say that a curve $d \in \mathcal{K}$ is *parabologenic* if for a Margulis tube V'_i in $\mathbf{M}_i$ with core curve homotopic to $k_i(d)$, we have $|\omega_{\mathbf{M}_i}(V'_i)| \to \infty$ passing to a subsequence, whereas $k_i^{-1} \circ f_i^{-1}(b_i)$ and d can be connected by a path α such that for any curve e in $\mathcal{K}$ that α passes, the Margulis tube V''_i with core curve $k_i(e)$ has the property that $\omega_{\mathbf{M}_i}(V''_i)$ is bounded as $i \to \infty$. A parabologenic curve always exists since c_i as above is a core curve of the Margulis tube V_i with $|\omega_{\mathbf{M}_i}(V_i)| \to \infty$. Choose a parabologenic curve d and a Margulis tube V'_i with core curve vertically homotopic to $k_i(d)$. Note that the diameters of split level surfaces modulo the Margulis tubes are universally bounded, and that b_i and V'_i can be connected by a path passing only through a split level surface and Margulis tubes with bounded $\omega_{\mathbf{M}_i}$. Therefore, the distance between b_i and V'_i is bounded as $i \to \infty$. Since $|\omega_{\mathbf{M}_i}(V'_i)| \to \infty$, the tubes V'_i converge geometrically to a cusp neighbourhood V'_∞ intersecting B.

Since V'_i is within distance D_S modulo the Margulis tubes from b_i, we see that V'_∞ cannot intersect the fronts of B by our choice of w_∞. Moreover, since d is a curve in $\mathcal{K}$, we see that $\rho^{\mathbf{M}}_i(k_i(d))$ cannot be homotopic to a curve on the vertical boundary of B. Therefore V'_∞ is a cusp in B whose longitude is not vertically homotopic into $\mathrm{Fr}\Sigma$. This contradicts the facts that B is a brick in the standard brick decomposition of $\mathbf{M}$ and that consequently B can intersect a cusp neighbourhood only at its vertical boundary and real front. □

Now we return to the proof of Lemma 4.16. Starting from a slice $\tau^i_{j(i)}$ in $R(b_i)$, we proceed in the resolution R_i. For any block b' in B, we consider the subfamily $R_i(b')$ of R_i consisting of slices τ^i_j with $j \geq j(i)$ such that the split level surface corresponding to τ^i_j intersects $(\rho^{\mathbf{M}}_i)^{-1}(b')$. By almost the same argument as in the proof of Claim 4.17, we can show the the number of slices contained in $R_i(b')$ is bounded as $i \to \infty$. The only difference of the argument for b' from that for b_i is that b' does not contain the basepoint w_∞. We used the assumption that b_i contains $(\rho^{\mathbf{M}}_i)^{-1}(w_\infty)$ in the proof of Claim 4.17 to show that the cusp neighbourhood V'_∞ does not touch the front of B. Since the end in B is upper, the front which we are considering is the lower one. Since we are considering a subsequence of R_i going forward from $j(i)$, the split level surfaces corresponding to the slices in $R_i(b')$ are above that corresponding to $\tau^i_{j(i)}$. This implies that a cusp neighbourhood appearing as a limit of Margulis tubes meeting these split level surfaces cannot intersect the lower front of B either. Similarly, we can show that for any Margulis tube or cusp neighbourhood V in B, the number of slices τ^i_j in R_i such that $j \geq j(i)$ and the split level surface corresponding to τ^i_j intersect $(\rho^{\mathbf{M}}_i)^{-1}(V)$ is bounded as $i \to \infty$.

Recall that the total number of the slices in R_i goes to ∞. For the split level surface $h(\tau^i_{j(i)})$ corresponding to $\tau^i_{j(i)}$, its image $\rho^{\mathbf{M}}_i(h(\tau^i_{j(i)}))$ is bounded distance from the lower front of B since it intersects b. Therefore there must be infinitely many blocks above $\rho^{\mathbf{M}}_i(h(\tau^i_{j(i)}))$. This implies that the number of slices τ^i_j with $j > j(i)$ goes to ∞ as $i \to \infty$. Suppose that the lengths of the main geodesics are bounded. This is possible only when there is a number j_1 independent of i such that for any n_0, there is i such that all the slices $\tau^i_{j(i)+j_1}, \dots, \tau^i_{j(i)+j_1+n_0}$ share the same pair $(g_{h_i(B)}, w_i)$ in R_i. Let V''_i be the Margulis tube whose core curve is vertically homotopic to a simple closed curve which is a component of w_i. Since V''_i is reached within j_1 steps from $\tau^i_{j(i)}$ intersecting b_i, the tube is within bounded distance from b_i. Therefore, passing to a subsequence $\{V''_i\}$ converge to a cusp neighbourhood V in B. This contradicts the fact shown above that the number of slices whose corresponding split level surfaces intersect $(\rho^{\mathbf{M}}_i)^{-1}(V)$ is bounded as $i \to \infty$. □

Now, we shall complete the proof of Proposition 4.9. By our definition of $h_i(B_i)$, we see that there is a geodesic γ_i in h_i with support Σ which contains the main geodesic $g_{h_i(B_i)}$ as a subgeodesic. Therefore, we have already proved the conditions (1) and (2). It remains to show the conditions (3) and (4).

The main geodesic of $h_i(B_i)$ penetrates B_i by Lemma 4.15. Since either $g_{h_i(B_i)}$ is a ray or the length of $g_{h_i(B_i)}$ goes to ∞, by Lemma 4.15 again, the first vertex of $g_{h_i(B_i)}$ coincides with that of γ_i for large i. This means that we can identify the limit of γ_i with that of $g_{h_i(B_i)}$.

As was remarked before, $(\rho^{\mathbf{M}}_i)^{-1} \circ g'$ is homotopic to $\Phi^{\mathbf{M}}_i$. For any i, there is a number $K(i)$ with $K(i) \to \infty$ such that the core curves of Margulis tubes in B within the distance $K(i)$ from the basepoint w_∞ are homotopic into $g'(S)$ within the range of the approximate isometry $\rho_i^{\mathbf{M}}$. It follows that there is a number $n(i)$ which goes to ∞ such that for each v_j^i among the first $n(i)$-simplices v_j^i of γ_i, a homotopy between $(\rho_i^{\mathbf{M}})^{-1} \circ g'(v_j^i)$ and the corresponding core curves of Margulis tubes in B_i can be pushed forward to a homotopy between $g'(v_j^i)$ and the core curves of the corresponding Margulis tubes in B. Note that any sequence of core curves of Margulis tubes going to the end of B converges to the ending lamination of the simply degenerate end. This implies that γ_i converges to a geodesic ray whose endpoint is the ending lamination uniformly on each one in an ascending exhausting sequence of compact sets in $[0, \infty)$, after passing to a subsequence, and we get the conditions (3) and (4) using Lemma 2.2.

4.4. **Non-algebraic simply degenerate ends.** In the proof of Proposition 4.9, we used the assumption that the end in B is algebraic only to show that the support of γ_i is Σ. Even in the case when the end in B may not be algebraic, the argument above shows that we still have a geodesic as γ_i in h_i, and its support is the preimage of Σ, which may depend on i. Thus we get the following corollary.

Corollary 4.18. *Let $B = \Sigma \times I$ be a simply degenerate brick of $\mathbf{M}$. Let $\mathcal{V}$ be the union of all boundary components of $\mathbf{M}$ touching the vertical boundary of B, and $\mathcal{V}_i$ the union of Margulis tubes corresponding to $(\rho_i^{\mathbf{M}})^{-1}(\mathcal{V} \cap B_{K_i r_i}(\mathbf{M}, x_\infty))$. Then, there is a geodesic γ_i in h_i satisfying the following conditions.*

1. *For sufficiently large i, the preimage $(\rho_i^{\mathbf{M}})^{-1}(B)$ is contained in a brick $B_i = \Sigma_i \times J_i$ in the standard brick decomposition of $\mathbf{M}_i \setminus \mathcal{V}_i$.*
2. *The geodesic γ_i is supported on Σ_i. Passing to a subsequence, we can assume that all γ_i either have finite lengths or are geodesic rays.*
3. *If the γ_i have finite lengths, their lengths go to ∞ as $i \to \infty$.*
4. *Let $\partial_{\mathrm{real}} B$ be the real front of B. Let $k_i : \Sigma \to \Sigma_i$ be a homeomorphism induced from $(\rho_i^{\mathbf{M}})^{-1} | \partial_{\mathrm{real}} B$. If γ_i has finite length, for the last vertex v_i of γ_i, its image $k_i^{-1}(v_i)$ on Σ converges to the ending lamination of the simply degenerate end of B. If γ_i is a ray, then for the endpoint e_i of γ_i at infinity, $k_i^{-1}(e_i)$ converges to the ending lamination of the end in B in $\mathcal{EL}(\Sigma)$.*

5. Limits of end invariants and ends of models

In this section, we consider the situation where $\{(G_i, \phi_i) = qf(m_i, n_i)\}$ converges to (Γ, ψ) in $AH(S)$ and $\{G_i\}$ converges geometrically to G_∞. We assume that $\{m_i\}$ converges to $[\mu^-]$ and $\{n_i\}$ converges to $[\mu^+]$ in the Thurston compactification of the Teichmüller space. Let Σ^- and Σ^+ be the boundary components of the convex core of $M_i = \mathbb{H}^3/G_i$ facing the upper and lower ends respectively. We shall first recall the following fact, which follows from the continuity of length function.

Lemma 5.1. *Let ν be a component of either μ^- or μ^+. If ν is a weighted simple closed curve, then $\Psi(|\nu|)$ represents a parabolic class of Γ. Otherwise, its image $\Psi(\nu)$ represents the ending lamination for an end of M_0'.*

Proof. This is just a combination of Thurston's theorem and the continuity of the length function proved by Brock [7] in general form. We can assume that ν is a component of μ^- since the argument for the case of μ^+ is exactly the same. Thurston's Theorem 2.2 in [39] (whose proof can be found in [18] and [40]) shows that there is a sequence of simple closed curve $r_i\gamma_i$ converging to μ^+ such that $\mathrm{length}_{m_i}(r_i\gamma_i)$ goes to 0. By Bers' inequality [4], this implies that $\mathrm{length}_{\Sigma_i^-}(r_i\gamma_i)$ also goes to 0.

By the continuity of the length function with respect to the algebraic topology (see Brock [7]), we have $\mathrm{length}_{M'}\Psi(\mu^-) = 0$, which means every component of $\Psi(\mu^-)$ represents either a parabolic class or an ending lamination. □

We shall refine this lemma to show that the components of the limit of $\{m_i\}$ appear as lower parabolics or lower ending laminations whereas those of $\{n_i\}$ appear as upper parabolics or upper ending laminations.

Theorem 5.2. *Let c_{m_i} and c_{n_i} be shortest (hyperbolic) pants decompositions of (S, m_i) and (S, n_i) respectively. Let ν^- and ν^+ be the Hausdorff limits of $\{c_{m_i}\}$ and $\{c_{n_i}\}$ respectively. Then the minimal components of ν^+ that are not simple closed curves coincide with the ending laminations of upper algebraic simply degenerate ends of $\mathbf{M}$. Moreover, no upper algebraic parabolic curve of $\mathbf{M}$, regarded as a curve on S, can intersect a minimal component of ν^+ transversely. Similarly the minimal components of ν^- that are not simple closed curves coincide with the ending laminations of lower algebraic simply degenerate ends of $\mathbf{M}$, and no lower algebraic parabolic curve can intersect a minimal component of ν^- transversely.*

Proof. We shall only deal with ν^+. The argument for ν^- is obtained only by turning $\mathbf{M}$ upside down. Let h_i be a hierarchy corresponding to $qf(m_i, n_i)$, and consider the model manifold $\mathbf{M}_i$ such that $M_i[k]$ converges geometrically to $\mathbf{M}[k]$ as before. We regard $\mathbf{M}$ as being embedded in $S \times [0,1]$ as usual.

We shall first show that the ending lamination of any upper algebraic simply degenerate end e of $\mathbf{M}$ is a minimal component of ν^+. Let $B = \Sigma \times [s,t)$ be a simply degenerate brick of $\mathbf{M}$ containing the end e. By Proposition 4.9, the hierarchy h_i contains a geodesic γ_i supported on Σ whose last vertex converges to the ending lamination λ_e of e in $\mathcal{UML}(S)$. Now, as was shown in §6 in Masur-Minsky [27] using Theorem 3.1 in the same paper, the distance between the last vertex of γ_i and the projection of the terminal marking $T(h_i)$ of h_i to Σ is uniformly bounded. In particular, for the shortest pants decomposition c_{n_i}, which consists of the base curves of $T(h_i)$, its projection to Σ converges to λ_e in $\mathcal{UML}(\Sigma)$. Since the Hausdorff limit of $c_{n_i}|\Sigma$ contains the limit of c_{n_i} in $\mathcal{UML}(\Sigma)$, this shows that the ending lamination of any upper algebraic simply degenerate end is contained in ν^+.

Secondly, we shall show that no upper algebraic parabolic curve can intersect a minimal component of ν^+ transversely. Let c be an upper parabolic curve on S. There are three cases which we have to consider. The first is the case (a) when $g'(c)$ is homotopic to a curve on a torus boundary of $\mathbf{M}$; the second is the case (b) when $g'(c)$ is homotopic to a core curve of an open annulus boundary component of $\mathbf{M}$ at least one of whose ends touches a geometrically finite end; and the third is the case (c) when $g'(c)$ is homotopic to a core curve of an open annulus boundary component whose ends touch only simply degenerate or wild ends.

(a) We first consider the case when the curve $g'(c)$ homotopic into a torus component T of $\mathbf{M}$. Let V_i be the Margulis tube bounded by $(\rho_i^{\mathbf{M}})^{-1}(T)$ in $\mathbf{M}_i$ for large i. Then $\Re\omega_{\mathbf{M}_i}(V_i)$ goes to ∞ whereas the imaginary part is bounded as $i \to \infty$. Let c_i be a simple closed curve on S whose image by $\Phi_i^{\mathbf{M}}$ is homotopic to the longitude of V_i. Since the longitude of ∂V_i converges to that of T which is homotopic to the image of a simple closed curve under g', the homotopy class of c_i is independent of i for large i. Therefore, by taking a subsequence, we can assume that c_i is constantly c. Let A be an annulus on S which is a regular neighbourhood of c. Since

$\Re\omega_{\mathbf{M}_i}(V_i) \to \infty$, there is a geodesic γ_i in h_i supported on A whose length goes to ∞ as $i \to \infty$. Let $a(i)$ and $b(i)$ be the first and last vertices of γ_i, and let $n(a)_i$ and $n(b)_i$ be the (signed) number of times $a(i)$ and $b(i)$ go around c compared to the transversal of the marking determined by $\Phi_i^{\mathbf{M}}$. Then $|n(b)_i - n(a)_i|$ goes to ∞ as $i \to \infty$. We set $n(i)$ to be $n(b)_i - n(a)_i$.

By the definition of hierarchy, there is a vertex of a geodesic g_i in h_i with $\xi(D(g_i)) = 4$ which represents c (and is denoted also by c), satisfying $\pi_A(\mathrm{prec}(c)) = a(i), \pi_A(\mathrm{succ}(c)) = b(i)$. As was shown above, the distance between $\pi_A(\mathrm{prec}(c))$ and $\pi_A(\mathrm{succ}(c))$ goes to ∞. Since these $\mathrm{prec}(c)$ and $\mathrm{succ}(c)$ may depend on i, we denote $\mathrm{prec}(c)$ in g_i by v_i and $\mathrm{succ}(c)$ in g_i by w_i.

Since there is an elementary move changing v_i to c, there is a block b_i in $\mathbf{M}_i$ realising this elementary move by the definition of model manifolds by Minsky [29]. Let V_i be the Margulis tube in $\mathbf{M}_i$ whose core curve represent v_i, and u_i a horizontal longitude on ∂V_i. Recall that the block decomposition of $\mathbf{M}_i$ converges geometrically to that of $\mathbf{M}$ as $i \to \infty$. Therefore, the block can be pushed forward to a block b_∞ in $\mathbf{M}$ for large i, and hence there is either a Margulis tube or a torus boundary in $\mathbf{M}$ whose core curve or longitude, which we denote by u_∞ is homotopic to $\rho_i^{\mathbf{M}}(u_i)$ for every large i. First suppose that g' does not go around T. Then g' can be homotoped so that it passes b_∞ horizontally, and consequently, there is a simple closed curve u on S such that $g'(u)$ is homotopic to u_∞. By pulling back this to $\mathbf{M}_i$, we see $\Phi_i^{\mathbf{M}}(u)$ is homotopic to $\mathrm{prec}(c)$ for large i. This means that $n(a)_i$ is bounded as $i \to \infty$, and hence $|n(b)_i|$ goes to ∞.

We next consider the case when g' goes k-times around T for $k \in \mathbb{Z} \setminus \{0\}$. Then, there is a simple closed curve u on S as above such that we can homotope $(\rho_i^{\mathbf{M}})^{-1} \circ g'(u)$ to u_i after passing k-times through V_i. This means that the $kn(i)$-time Dehn twist of u_i around c represents a constant homotopy class for large i. Therefore, $|n(a)_i|$ grows in the order of $|kn(i)|$ and $|n(b)_i|$ in the order of $|(k+1)n(i)|$ in this case.

In either case, we see that $|n(b)_i|$ goes to ∞. Therefore, by §6 of [27] again, the projection of the shortest pants decomposition c_{n_i} to $\mathcal{CC}(A)$ also goes around $n'(i)$ times around c with $n'(i) \to \infty$. This shows that the Hausdorff limit ν^+ of $\{c_{n_i}\}$ contains c as a minimal component.

(b) Next we consider the second case when $g'(c)$ is homotopic to a core curve of an open annulus boundary component T which touches a geometrically finite end e of $\mathbf{M}$. The end e corresponds to $\Sigma \times \{1\}$ for some essential subsurface Σ of S and has some conformal structure n_Σ. By the definition of conformal structures on the geometrically finite bricks of $\mathbf{M}$, there is a subsurface Σ_i in S such that (Σ_i, n_i) converges to (Σ, n_Σ) geometrically. Since T is assumed to be algebraic, a frontier component c of Σ is pulled back to a frontier component c_i of Σ_i such that $\Phi_i^{\mathbf{M}}(c)$ is homotopic to c_i. This implies that the length of c with respect to n_i goes to 0, and the pants decomposition c_{n_i} must contain c. Therefore c is contained in the Hausdorff limit of $\{c_{n_i}\}$ also in this case.

(c) Now, we consider the third case when $g'(c)$ is homotopic to a core curve of an open annulus boundary component T whose ends touch only simply degenerate or wild ends. Suppose, seeking a contradiction, that there is a minimal component d of ν^+ intersecting c transversely. By the argument of the case (a) above, we see that d cannot intersect an upper algebraic parabolic curve on S whose image by g' is homotopic into a torus boundary component.

We shall first show that there is a simply degenerate end corresponding to $\Sigma\times\{t\}$ lying above $g'(S)$ and an essential surface F containing d such that $g'(F\cap\Sigma)$ is vertically homotopic to $\Sigma\times\{t-\epsilon\}$ for any small ϵ, and d intersects $F\cap\Sigma$ essentially. (Here $F\cap\Sigma$ is assumed to have no inessential intersection. This can be achieved by making their frontiers geodesic with respect to some fixed hyperbolic metric on S.) Suppose first that there is an upper algebraic simply degenerate end corresponding to $\Sigma\times\{t\}$ such that Σ intersects d essentially. (This is equivalent to saying that d intersects the minimal supporting surface of an upper ending lamination essentially.) Then, by letting F be the entire S, the condition above holds.

Suppose next that d can be homotoped to be disjoint from any minimal supporting surface of the upper ending lamination (i.e. Σ for algebraic simply degenerate ends as above). Let F be a component of the complement in S of the union of the minimal supporting surfaces of the upper ending laminations and annular neighbourhoods of parabolic curves of the case (a) above, which contains d. Since c cannot intersect the minimal supporting surface of an upper ending lamination and a parabolic curve of (a) above, c is also contained in F. Consider simply degenerate ends or a lower horizontal annulus of a torus boundary corresponding to $\Sigma'\times\{t\}$ above $g'(S)$ such that Σ' intersects d essentially. We can see that such ends exist since the boundary component into which $g'(c)$ is homotopic touches either a simply degenerate end or a wild end and there is no essential half-open annulus tending to a wild end. We take a lowest one among such $\Sigma'\times\{t\}$, and denote it by $\Sigma\times\{t\}$. Then $(\Sigma\cap F)\times\{t-\epsilon\}$ is homotopic to $g'(\Sigma\cap F)$ in $\mathbf{M}$ for any small positive ϵ. (See Figure 3.)

Suppose first that the end corresponding to $\Sigma\times\{t\}$ is simply degenerate, and denote it by e. Let λ be the ending lamination of the end e, and B the brick of $\mathbf{M}$ containing e. By Corollary 4.18, there are bricks $B_i\cong\Sigma_i\times J_i$ containing $(\rho_i^{\mathbf{M}})^{-1}(B)$ and geodesics γ_i supported on Σ_i whose length goes to ∞ as $i\to\infty$. The approximate isometry induces a homeomorphism $f_i:\Sigma\to\Sigma_i$. Also, we know that for the last vertex t_i of γ_i, its image $(f_i)^{-1}(t_i)$ converge to the ending lamination λ. By the same argument as before using §6 of [27], we see that $\{(f_i)^{-1}\pi_{\Sigma_i}(c_{m_i})\}$ converges to λ.

Since $g'(F\cap\Sigma)$ is vertically homotopic into $\Sigma\times\{t-\epsilon\}$ in $\mathbf{M}$ for any small positive ϵ, we see that $f_i|(F\cap\Sigma)$ is homotopic to the identity map on $F\cap\Sigma$. Since λ is arational in Σ, and Σ intersects d essentially, we see that λ intersects d essentially. On the other hand, $\{f_i^{-1}(c_{m_i})\}$ converges to a geodesic lamination containing λ whereas $\{c_{m_i}\}$ converges to ν containing d, both in the Hausdorff topology. Considering the fact that $f_i|F\cap\Sigma$ is homotopic to the identity, we see that this is impossible.

Next suppose that $\Sigma\times\{t\}$ lies on a torus boundary component T. Then Σ is an annulus. Let Σ_i be the lower horizonal annulus on $\rho_i^{-1}(T)$. Then by the same argument as in the case (a), we see that $\pi_{\Sigma_i}(c_{n_i})$ spirals around the core curve of Σ_i more and more as $i\to\infty$. Since $(\Sigma\cap F)\times\{t-\epsilon\}$ is homotopic to $g'(\Sigma\cap F)$ and $\Sigma\cap F$ intersects d essentially , this shows that the Hausdorff limit of $\{c_{n_i}\}$ intersects d transversely. This is a contradiction. Thus we have shown that an upper algebraic parabolic curve cannot intersect a minimal component of ν^+ transversely.

To complete the proof, it remains to show that ν^+ has no minimal component that is not a compact leaf and is disjoint from the minimal supporting surfaces of

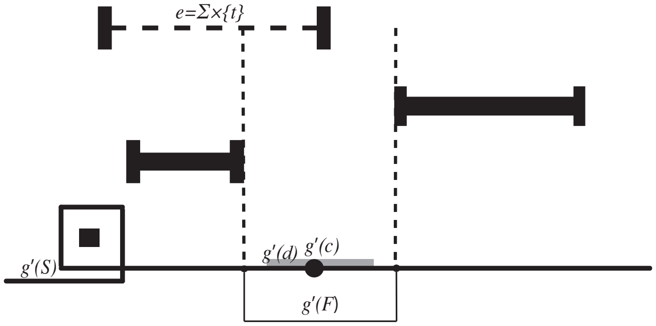

Figure 3. The definition of F and the lowest end

the ending laminations of upper algebraic simply degenerate ends. We also recall that no minimal component of ν^+ intersects an upper parabolic locus regarded as lying on S, as has been shown above. Let $\Sigma_1, \dots, \Sigma_{j_0}$ be the minimal supporting surfaces of the ending laminations of upper algebraic simply degenerate ends. (We take these so that their boundaries are totally geodesic with respect to the fixed hyperbolic metric on S.) Let F be a component of the complement of the union of $\cup_{j=1}^{j_0} \Sigma_j$ and all upper parabolic loci, which we take to be geodesics. What we have to show is that every minimal component d of ν^+ contained in F is a simple closed curve.

The argument is quite similar to that of the case (c) above. Before dealing with the general situation, we begin with considering the special case when $g'(F)$ is homotopic into an end lying above $g'(S)$. The end cannot be wild since there is no essential open annulus tending to the end, hence is either geometrically finite or simply degenerate. Then there is an incompressible subsurface S' of S containing F such that $g'(F)$ is homotopic into an end corresponding to $S' \times \{s\}$ (i.e. into $S' \times \{s - \epsilon\}$ for any small positive ϵ), where $s = 1$ if the end is geometrically finite. We first consider the case when $s = 1$ and $S' \times \{1\}$ is geometrically finite. By our definition of geometrically finite ends of $\mathbf{M}$, the surface $S' \times \{1\}$ has a hyperbolic metric n_∞ which is a geometric limit of (S, n_i) with base point lying in the thick part of $(S'_i, n_i|S'_i)$ for some subsurface S'_i homeomorphic to S'. Since $F \times \{1 - \epsilon\}$ in $\mathbf{M}$ is homotopic to $g'(F)$, we see that S'_i contains F for large i and that $n_i|F$ converges to $n_\infty|F$ preserving the markings. Note that $\nu^+|F$ is a Hausdorff limit of $c_{n_i}|F$ and d is contained in it. Since $n_i|F$ converges to n_∞, we see that a minimal component of the Hausdorff limit ν^+ of $\{c_{n_i}\}$ contained in F must be a compact leaf.

Next suppose that there is a simply degenerate end e of $\mathbf{M}$ of the form $S' \times \{s\}$ lying above $g'(S)$ into which $g'(F)$ is homotopic. Then this end cannot be algebraic since F lies in the complement of the minimal supporting surfaces of ending laminations of upper algebraic simply degenerate ends. Let B be a simply degenerate brick containing $S' \times \{s\}$, and λ_e the ending lamination of e. Since $S' \times \{s\}$ is not algebraic, F is an essential subsurface of S'. Now, by Corollary 4.18, there is a brick of the form $S'_i \times [s_i, t_i]$ in $\hat{\mathbf{M}}_i$ containing $(\rho_i^{\mathbf{M}})^{-1}(B \cap B_{K_i r_i}(\mathbf{M}, x_\infty))$ in which a tube union corresponding to a geodesic γ_i is put. Also, for a homeomorphism $f_i : S' \to S'_i$ induced from $(\rho_i^{\mathbf{M}})^{-1}|\partial_{\mathrm{real}} B$, the image of the last vertex or the lamination corresponding to the endpoint at infinity of γ_i under f_i^{-1} converges to the ending lamination λ_e. By the same argument as before using §6 of [27], this implies that $f_i^{-1}(\pi_{S'_i}(c_{n_i}))$ converges to λ_e. Now, since $g'(F)$ is homotopic into $S' \times \{s\}$ and λ_e is arational, this shows that the Hausdorff limit of $\{c_{n_i}|F\}$ consists only of arcs. Therefore, F cannot contain d, contradicting our assumption.

In general, as in the argument of (c) above, there is a simply degenerate end or a horizontal annulus on a torus boundary component, corresponding to $\Sigma \times \{t\}$ situated above $g'(S)$, such that $g'((F \cap \Sigma) \times \{t-\epsilon\})$ is homotopic into $g'(F)$ in $\mathbf{M}$ for any small positive ϵ and $\mathrm{Fr}(F \cap \Sigma)$ intersects d essentially. (See Figure 3 again.) Suppose first that $\Sigma \times \{t\}$ corresponds to a simply degenerate end e. Then as in the argument in (c) above, $c_{n_i}|(F \cap \Sigma)$ must converge to the restriction of the ending lamination λ_e of e to F. Since $\mathrm{Fr}(F \cap \Sigma)$ intersects d essentially and λ_e is arational in Σ, this shows that the Hausdorff limit of $c_{n_i}|(F \cap \Sigma)$ intersects d transversely. This is a contradiction.

Next suppose that $\Sigma \times \{t\}$ lies on a torus boundary component T. As in the argument in (a) and (c) above, the Hausdorff limit of $c_{n_i}|F$ has a leaf running along $F \cap \Sigma$. Since $F \cap \Sigma$ intersects d essentially, this again implies that the Hausdorff limit of c_{n_i} intersects d transversely, which is a contradiction again. Thus we have shown that every minimal component of the Hausdorff limit of $\{c_{n_i}\}$ contained in F is a compact leaf. This completes the proof of Theorem 5.2. □

Theorem 2 in §3 is obtained as a corollary of Theorem 5.2, as follows.

Proof of Theorem 2. Each simply degenerate end of $\mathbf{M}$ is mapped to that of $(M_\infty)_0$. Let $p : M' \to M_\infty$ be a covering associated to the inclusion of the algebraic limit Γ into the geometric limit G_∞. By the covering theorem of Thurston [38] and Canary [14], each simply degenerate end of $(M')_0$ has a neighbourhood which is mapped homeomorphically to a neighbourhood of a simply degenerate end of $(M_\infty)_0$. Furthermore the ending lamination of an end of $(M')_0$ is identified with that of the corresponding end of $(M_\infty)_0$ by p, which follows immediately by the definition of ending laminations. Therefore the algebraic simply degenerate ends of $\mathbf{M}$ correspond to simply degenerate ends of $(M')_0$ one-to-one preserving the ending laminations. It is also obvious that upper (resp. lower) ends of $\mathbf{M}$ correspond to upper (resp. lower) ends of $(M')_0$. Similarly the algebraic parabolic curves correspond to the core curves of the parabolic loci of M'. These show that Theorem 2 follows from Theorem 5.2. □

Lemma 5.3. *Let $\{g_i\}$ be a sequence in the Teichmüller space $\mathcal{T}(S)$ which converges to a projective lamination $[\mu]$ in the Thurston compactification. Let c_i be a pants decomposition on (S, g_i) whose total length is uniformly bounded. Then the Hausdorff limit of any subsequence of $\{c_i\}$ contains all the components of $|\mu|$ as minimal components.*

Proof. Let λ be the Hausdorff limit of a convergent subsequence of $\{c_i\}$. Since c_i is pants decomposition of S, there is no measured lamination on S which is disjoint from c_i, other than the components of c_i. Therefore there is no measured lamination on S which is disjoint from λ, other than minimal components of λ. Let μ_0 be a component of μ, and suppose that its support is not a minimal component of λ. Then μ_0 must intersect λ essentially.

We shall first consider the case when μ_0 is not a simple closed curve. Let Σ be the minimal supporting surface of μ_0. We consider a sequence of essential arcs and simple closed curves $c_i \cap \Sigma$ on Σ. Note that $c_i \cap \Sigma$ converges to $\lambda \cap \Sigma$ with respect to the Hausdorff topology, which is non-empty. If $\lambda \cap \Sigma$ contains a minimal component contained in $\mathrm{Int}\Sigma$, then there is a sequence of positive numbers r_i going to 0 such that $r_i c_i \cap \Sigma$ converges to a measured lamination γ in Σ. Otherwise we can find a bounded sequence of positive numbers r_i such that $\{r_i c_i\}$ converges to a union γ of essential arcs. (The limit is taken in the space of weighted essential curves in Σ with the weak topology.) In either case, let R be $\max_i r_i$. Now, $\mathrm{length}_{g_i}(c_i) \geq r_i \mathrm{length}_{g_i}(c_i)/R$, where the right hand goes to ∞ since $i(\mu_0, \gamma) > 0$ and an arc with non-zero intersection with the Thurston limit has length going to ∞ if we consider hyperbolic structures on Σ with geodesic boundaries. This implies that $\mathrm{length}_{g_i}(c_i)$ must also go to ∞, which is a contradiction.

Next suppose that μ_0 is a simple closed curve. If the length of μ_0 with respect to n_i goes to 0, then we can take an annular neighbourhood $A_i(\mu_0)$ of μ_0 whose width (with respect to n_i) goes to ∞ as $i \to \infty$. Since λ intersects μ_0 essentially, c_i passes through $A_i(\mu_0)$ for large i. This implies the length of c_i in (S, n_i) goes to ∞, which is a contradiction. Next suppose that the length of μ_0 is bounded from both above and below by positive constants. Then we can take an annular neighbourhood $A_i(\mu_0)$ whose width is bounded away from 0. Consider the shortest essential arc α_i in $A_i(\mu_0)$. Since μ_0 is contained in the limit lamination $[\mu]$ of $\{g_i\}$, the shortest arc α_i must spirals around μ_0 more and more as $i \to \infty$. Since λ does not contain μ_0, the number of spiralling of c_i around μ_0 is bounded. This means twisting number between α_i and $c_i|A_i(\mu_0)$ goes to ∞. Therefore, the length of $c_i|A_i(\mu_0)$ goes to ∞ as $i \to \infty$. In the case when the length of μ_0 goes to ∞, we take $A_i(\mu_0)$ whose width goes to 0 as $i \to \infty$. Also in this case, the shortest essential arc α_i spirals around μ_0 more and more as $i \to \infty$. Since the twisting number between α_i and $c_i|A_i(\mu_0)$ goes to ∞ also in this case, we see that the length of $c_i|A_i(\mu_0)$ goes to ∞. This is a contradiction. □

Combining this lemma with Theorem 5.2, we get the following corollary.

Corollary 5.4. *Let* $[\mu^+]$ *and* $[\mu^-]$ *be projective laminations to which* $\{m_i\}$ *and* $\{n_i\}$ *converge in the Thurston compactification of* $\mathcal{T}(S)$ *after taking subsequences. Then each minimal component of* $|\mu^+|$ *is either the ending lamination of an upper algebraic simply degenerate end or an upper algebraic parabolic curve of* $\mathbf{M}$*. Similarly, each component of* $|\mu^-|$ *is either the ending lamination of a lower algebraic simply degenerate end or a lower algebraic parabolic curve of* $\mathbf{M}$*.*

Proof. Each component of $|\mu^+|$ that is not a simple closed curve is the ending lamination of an upper simply degenerate end by Theorem 5.2 and Lemma 5.3. Let c be a component of $|\mu^+|$ which is a simple closed curve. Then by Lemma 5.1, $\psi(c)$ is parabolic. Therefore c is an algebraic parabolic locus in $\mathbf{M}$. It remains to show that c is upper.

Suppose that c is not upper, seeking a contradiction. This assumption implies, in particular, that if c is isolated and is homotopic to a curve lying on a torus boundary T of $\mathbf{M}$, then the standard algebraic immersion g' does not go around T. Since there is no essential half-open annulus tending to a wild end, there are only three possibilities for the curve $g'(c)$: (1) the first is when c lies in a domain F of S as a non-peripheral curve and $g'(F)$ is homotopic into some simply degenerate end above $g'(S)$, (2) there exists F containing c as above such that $g'(F)$ is homotopic into geometrically finite end, lying on $S \times \{1\}$, and (3) the third is when there is an upper algebraic parabolic curve intersecting c essentially on S.

(1) Suppose that $g'(F)$ is homotopic into a simply degenerate end e. Then its ending lamination λ_e intersects c essentially. We shall argue as in the proof of Theorem 5.2, where we dealt with the case when $g'(\Sigma')$ is homotopic into a simply degenerate end. Let $B = S' \times [s,t)$ be a simply degenerate brick of $\mathbf{M}$ containing e. By Corollary 4.18, there are a brick $B_i = S'_i \times [s_i, t_i]$ in $\hat{\mathbf{M}}_i$ containing $(\rho_i^{\mathbf{M}})^{-1}(B \cap B_{K_i r_i}(\mathbf{M}, x_\infty))$ and a geodesic γ_i in h_i supported on S'_i which induces a tube union in B_i. As before there is a homeomorphism $f_i : S' \to S'_i$ induced from $(\rho_i^{\mathbf{M}})^{-1}|\partial_{\mathrm{real}} B$, such that for the last vertex v_i of γ_i its image $f_i^{-1}(v_i)$ converges to λ_e.

Let $A(c)$ be an annulus with core curve c. Since F is homotopic into e, we see that $f_i|F$ is homotopic to the identity. In particular, we can assume that $f_i|A(c)$ is the identity. Therefore $v_i|A(c) = f_i^{-1}(v_i)|A(c)$ converges to some vertex in $\mathcal{CC}(A(c))$, corresponding to $\pi_{A(c)}(\lambda_e)$. This implies, again by the argument of §6 of Masur-Minsky [27], that $\{c_{n_i}|A(c)\}$ converges to some vertex in $\mathcal{CC}(A(c))$ after passing to a subsequence. On the other hand, by Lemma 5.3, $\{c_{n_i}\}$ must converge to a lamination containing c in the Hausdorff topology. This is a contradiction.

(2) In the second case, $g'(F)$ is homotopic into an upper geometrically finite end of $\mathbf{M}$. Take a simple closed curve δ on F intersecting c essentially. Since $g'(\delta)$ is homotopic to a curve in an upper geometrically finite end, which is a geometric limit of (S, m_i) with base point in F, we see that $\mathrm{length}_{m_i}(\delta)$ is bounded as $i \to \infty$. This contradicts the assumption that c is contained in μ^+.

(3) In the third case, let d be an upper algebraic parabolic curve with $i(c,d) > 0$. Recall that c is a minimal component of the Hausdorff limit ν^+ of $\{c_{m_i}\}$ by Lemma 5.3. Therefore, d intersects a minimal component of ν^+ transversely in this situation, contradicting Theorem 5.2. Thus we have completed the proof. □

6. Proofs of Theorem 1, Theorem 3 and Theorem 5

We can now prove Theorem 1, Theorem 3 and Theorem 5 making use of our results in the previous section.

6.1. **Proof of Theorem 1.**

We consider the geometric limit M_∞ of M_i and the model $\mathbf{M}$ of its non-cuspidal part as before. By the definition of algebraic simply degenerate ends of $\mathbf{M}$, they are mapped to simply degenerate ends of $(M_\infty)_0$ which lift to those of the algebraic limit $(M')_0$. Upper ends among them are mapped to those lifted to upper ends of $(M')_0$, and lower ones to those lifted to lower ends of $(M')_0$. Now, by Corollary 5.4, every component of $|\mu^+|$ that is not a simple closed curve is the ending lamination of an upper algebraic simply degenerate end. Therefore, it is the ending lamination of a upper simply degenerate end of $(M')_0$. The same argument works for $|\mu^-|$.

The second paragraph of the statement also follows immediately from Corollary 5.4.

6.2. **Proof of Theorem 3.**

Suppose, seeking a contradiction, that $\{qf(m_i, n_i)\}$ as in the statement of Theorem 3 converges after taking a subsequence. Then by Theorem 1, μ_0^+ is an ending lamination of an upper end of $(M')_0$ and μ_0^- is that of a lower end of $(M')_0$. Let Σ^+ and Σ^- be the minimal supporting surfaces of μ_0^+ and μ_0^- respectively, which were assumed to share at least one boundary component c.

Since c lies on the boundary of both Σ^- and Σ^+, it represents a $\mathbb{Z}$-cusp both above and below $\Psi(S)$. This is impossible since no two distinct cusps have homotopic core curves.

6.3. **Proof of Theorem 5.** As in the statement, let μ^- and μ^+ be two measured laminations on S whose supports share only simple closed curves $c_1, \ldots, c_r$. By our assumption, there is a component μ_0 of either μ^+ or μ^- whose minimal supporting surface $\Sigma(\mu_0)$ has some c_j among $c_1, \ldots, c_r$ on its frontier. We can assume that μ_0 is a component of μ^+ since the other case can be deal with in the same way just turning everything upside down.

By Corollary 5.4 a curve c_j shared by μ^- and μ^+ is both upper and lower algebraic parabolic curve. On the other hand, by Corollary 5.4, there is an upper algebraic simply degenerate end of $\mathbf{M}$ in the form $\Sigma(\mu_0) \times \{t\}$ which has $|\mu_0|$ as the ending lamination. This implies that there is a boundary component of $\mathbf{M}$ which is an open annulus with core curve homotopic to c_j. By Lemma 4.4, this shows that c_j cannot be a lower algebraic parabolic curve. This is a contradiction, and we have completed proof of Theorem 5.

7. Proof of Theorem 6

7.1. **Necessity.** We shall first show that the condition (1) is necessary. Suppose, on the contrary, that there is c_j among $c_1, \ldots, c_r$ such that $\mathrm{length}_{n_i}(c_j)$ goes to 0 whereas $\{(G_i, \phi_i) = qf(m_i, n_i)\}$ converges. (The argument for the case when $\mathrm{length}_{m_i}(c_j)$ goes to 0 is quite the same.) Let G_∞ be the geometric limit of a subsequence of $\{G_i\}$ as before, and set $M_i = \mathbb{H}^3/G_i$ and $M_\infty = \mathbb{H}^3/G_\infty$. Consider the model manifold $\mathbf{M}$ of $(M_\infty)_0$. By Corollary 5.4, c_j is an upper algebraic parabolic curve. Let $g' : S \to \mathbf{M}$ be a standard algebraic immersion. Since $\mathrm{length}_{n_i}(c_j) \to 0$, the boundary blocks of $\mathbf{M}_i$ corresponding to the upper boundary are pinched along an annulus with core curve c_j and are split in the geometric limit. By pushing forward this core curve and $\Phi_i(c_j)$ to M_∞ and pull it back to $\mathbf{M}$, we get a homotopy between a core curve of an open annulus component of $\partial\mathbf{M}$ and $g'(c_j)$. By Lemma 4.4, this shows $g'(S)$ cannot go around a torus boundary component whose longitude corresponds to c_j. In particular, c_j cannot be a lower algebraic parabolic curve. This contradicts, by way of Corollary 5.4, the fact that $|\mu_-|$ also contains c_j. This completes the proof of the necessity of the condition (1).

Next we turn to show the necessity of the condition (2). By Corollary 5.4 again, we see that if $\{(G_i, \phi_i)\}$ converges algebraically, each of $c_1, \ldots, c_r$ must be both upper and lower algebraic parabolic curve. By Lemma 4.4, this is possible only when $g'(S)$ goes around a torus boundary component T_j of $\mathbf{M}$ whose longitude is homotopic to $g'(c_j)$ for each $j = 1, \ldots, r$. Suppose that $g'(S)$ goes a_j times around T_j for $a_j \in \mathbb{Z}\setminus\{0\}$, where we define the counter-clockwise rotation to be the positive direction in Figure 1. As a convention we define the condition $a_j = 0$ means that $g'(S)$ passes below T_j. If $g'(S)$ passes above T_j not going around it, we define a_j to be -1.

Let $\mathbf{M}_i$ be a model manifold of $(M_i)_0$. Since $\mathbf{M}_i[0]$ converges to $\mathbf{M}[0]$ geometrically, there is a torus boundary $T_j(i)$ of $\mathbf{M}_i[0]$ which is mapped to T_j by the approximate isometry $\rho_i^{\mathbf{M}}$. The torus $T_j(i)$ consists of two horizontal annuli and two vertical annuli. We choose an oriented meridian-longitude system of T_j in such a way that the longitude l_j lies on a horizontal annulus and the meridian m_j is shortest among all the simple closed curves on T_j intersecting the longitude at one point. We define the orientation of l_j so that the positive direction of l_j is induced by the right-hand twist around c_j. By pulling back this system using the approximate isometry $\rho_i^{\mathbf{M}}$ between $\mathbf{M}_i[0]$ and $\mathbf{M}[0]$, we get a longitude $l_j(i)$ and a meridian $m_j(i)$ on $T_j(i)$. There is a Margulis tube $V_j(i)$ attached to $T_j(i)$ in $\mathbf{M}_i$. The compressing curve of $V_i(j)$ intersects the longitude $l_j(i)$ only at one point. Therefore we can express the homology class of the compressing curve as $k_i[l_j(i)] + [m_j(i)]$. Since $T_j(i)$ converges geometrically to a torus boundary component of $\mathbf{M}$, we have $|k_i| \to \infty$.

Fix some j and consider c_j. In $\mathbf{M}$, there is a block B^+ intersecting T_j by an annulus A^+ containing the upper horizontal annulus of T_j in the middle. Similarly, there is a block B^- intersecting T_j by an annulus A^- containing the lower horizontal annulus of T_j in the middle. One or both of these may be boundary blocks. We shall only consider the case when $a_j > 0$, i.e. the case when $g'(S)$ goes around T_j counter-clockwise in Figure 1. Since c_j is an algebraic parabolic curve, the standard immersion passes through both B^- and B^+.

Now, consider a simple closed curve γ^- in B^- which is homotopic to a core curve the lower horizontal annulus if B^- is an internal block. When B^- is a boundary block, we consider horizontal upper boundary components of B^- adjacent to A^-. If c_j is separating, there are two such surfaces, whose union we denote by Δ^-, and if c_j is non-separating there is only one such surface, which we denote by Δ^-. We take a simple closed curve γ^- which lies in $A^- \cup \Delta^-$ and intersect the core curve of A^- at two points when c_j is separating and at one point when c_j is non-separating. We define γ^+ in the same way. By pulling back γ^+ and γ^- by $(\rho_i^{\mathbf{M}})^{-1}$, we get simple closed curves $\gamma^+(i)$ and $\gamma^-(i)$. Using the vertical projection to S in $\mathbf{M}_i$, we regard $\gamma^+(i)$ and $\gamma^-(i)$ also as curves on S.

Let $g'_i : S \to \mathbf{M}_i$ be a pull-back of the standard immersion g' obtained by composing $(\rho_i^{\mathbf{M}})^{-1}$. We consider to homotope g'_i to unwrap it around $T_j(i)$ and make the surface pass under $T_j(i)$, by making it pass a_j times through $V_j(i)$. Let g''_i be a surface obtained by modifying the part of g'_i going around $T_j(i)$ to a horizontal surface and giving a natural marking coming from the structure of $S \times I$, which is equal to a marking determined by a pull-back of a horizontal surface in $\mathbf{M}$ obtained by removing the parts of g' going around torus boundaries. Note that g''_i and g'_i are not homotopic as maps because of the difference of markings. (This means that g''_i is not homotopic to $\Phi_i^{\mathbf{M}}$.) Each time $g'_i(S)$ passes through $V_j(i)$, a curve δ on S intersecting c_j is twisted k_i-times around c_j. (It goes $|k_i|$-times around c_i in the same direction as l_i if $k_i > 0$ and in the opposite direction if $k_i < 0$.) Since $\gamma^-(i)$ is homotopic to $g''_i(\gamma^-)$, we see that $g'_i(\tau_{c_j}^{k_i a_j}(\gamma^-))$ is homotopic to $\gamma^-(i)$. Similarly, since $\gamma^+(i)$ is homotopic to $g''_i(\tau^{k_i}(\gamma^+))$, we see that $g'_i(\tau_{c_j}^{k_i(a_j+1)}(\gamma^+))$ is homotopic to $\gamma^+(i)$.

Let h_i be a hierarchy of tight geodesics for $\mathbf{M}_i$ as before. Since $V_j(i)$ appears as a Margulis tube in $\mathbf{M}_i$, we see that an annular neighbourhood $A(c_j)$ of c_j supports a geodesic $\gamma_i(c_j)$ in h_i. By the definition of gluing blocks in Minsky [29], we see that $\pi_{A(c_j)}(\gamma^-(i))$ is the initial marking and $\pi_{A(c_j)}(\gamma^+(i))$ is the terminal marking of $\gamma_i(c_j)$ if both B^- and B^+ are interior blocks. By §6 of Masur-Minsky [27], this implies that $\pi_{A(c_j)}(I(h_i))$ is in a uniformly bounded distance from $\pi_{A(c_j)}(\gamma^-(i))$ and $\pi_{A(c_j)}(T(h_i))$ is in a uniformly bounded distance from $\pi_{A(c_j)}(\gamma^+(i))$. Even when B^- or B^+ is a boundary block, we have the same property: for, since the length of $\gamma^-(i)$ or $\gamma^+(i)$ is bounded, its projection to $A(c_j)$ is within bounded distance from those of $I(h_i)$ or $T(h_i)$. Since g_i' is homotopic to Φ_i for large i, we see that $\pi_{A(c_j)}(I(h_i))$ is within a uniformly bounded distance from $\pi_{A(c_j)}(\tau_{c_j}^{k_i a_j}(\gamma^-))$, whereas $\pi_{A(c_j)}(T(h_i))$ is within a bounded distance from $\pi_{A(c_j)}(\tau_{c_j}^{k_i(a_j+1)}(\gamma^+))$. This shows that if we consider the pushed-forward metrics $(\tau_{c_j}^{-k_i a_j})_* m_i$ and $(\tau_{c_j}^{-k_i(a_j+1)})_* n_i$ instead of m_i and n_i, then $\pi_{A(c_j)}(\gamma^+)$ is within a bounded distance from the projection of the terminal marking and $\pi_{A(c_j)}(\gamma^-)$ is within a bounded distance from that of the initial marking. By Lemma 5.3, this implies that the limits of $(\tau_{c_j}^{-k_i a_j})_* m_i$ and $(\tau_{c_j}^{-k_i(a_j+1)})_* n_i$ in the Thurston compactification of $\mathcal{T}(S)$ do not contain c_j as a leaf. We repeat the same argument for every c_j, and let p_i^j and q_i^j be $-k_i a_j$ and $-k_i(a_j+1)$ respectively. This completes the proof of the necessity.

It is clear that if $a_j \leq 0$, then c_j is an upper parabolic curve since g' goes around the torus containing c_j in the counter-clockwise and $f(c_j)$ is lifted to a curve lying above the core surface obtained the lift of $f \circ g'$ in M'. This shows that c_j is a core curve of an upper parabolic locus if $a_j \geq 0$. We can argue in the same way also when $a_j < 0$.

7.2. **Existence.** We shall next show that the existence of limits of quasi-Fuchsian groups satisfying the conditions (1) and (2). Our construction just follows the argument of Anderson-Canary [2].

We first construct a geometrically finite Kleinian group Γ_0 such that $N = \mathbb{H}^3/\Gamma_0$ is homeomorphic to the complement of $c_j \times \{1/2\}$ $(j = 1, \ldots, r)$ in $S \times [0,1]$, and the conformal structures corresponding to the ends $S \times \{0\}$ and $S \times \{1\}$ are the same point $m_0 \in \mathcal{T}(S)$. (Here we identify S with $S \times \{0\}$ and $S \times \{1\}$ by the natural inclusions.) We consider an immersion $g_0 : S \to N_0$ which is in the standard form in the sense of Lemma 4.4 , and wraps a_j times around each $c_j \times \{1/2\}$ counted counter-clockwise as in Figure 1 when we identify N_0 with its embedding in $S \times [0,1]$.

Next, we consider a quasi-conformal deformation of Γ_0. Let $\mu_1^-, \ldots, \mu_s^+$ and $\mu_1^+, \ldots \mu_t^+$ be the components of μ^- and μ^+ that are not the shared simple closed curves. We define a Kleinian group Γ_k to be one obtained by deforming the conformal structures m_0 on $S \times \{0\}$ by the earthquake with respect to $k(\cup_{j=1}^s \mu_j^-)$ and m_0 on $S \times \{1\}$ by the earthquake with respect to $k(\cup_{j=1}^t \mu_j^+)$. Let N_k be $\mathbb{H}^3/\Gamma_k$ and $h_k : N \to N_k$ a natural homeomorphism derived from the quasi-conformal deformation. We regard N_k also as embedded in $S \times [0,1]$ in such a way that the images of drilled out curves lie on $S \times \{1/2\}$, and the natural identification of this $S \times [0,1]$ with the one in which N is embedded is compatible with h_k. Then we get an immersion $g_k : S \to N_k$ which is defined to be the composition $h_k \circ g_0$.

In the manifold N, every essential annulus either intersects a torus cusp or $\mu^+ \cup \mu^-$, or has boundary contained in a component of $S \times \{0\} \setminus \mu^-$, $S \times \{1\} \setminus \mu^+$, where the conformal structure is not deformed, by the conditions (1*), (2*), and (3*). Therefore, by the main theorem of [31], we see that N_k with marking determined by h_k converges algebraically to a hyperbolic 3-manifold $N_\infty = \mathbb{H}^3/\Gamma_\infty$ with a homeomorphism $h_\infty : N \to N_\infty$. The laminations $\mu_1^-, \ldots, \mu_s^-; \mu_1^+, \ldots, \mu_t^+$ represent ending laminations of simply degenerate ends. The convergence is strong, by the covering theorem of Thurston and Canary ([38], [14]) combined with Abikoff's Lemma 3 in [1]. Let $g_\infty : S \to N_\infty$ be an immersion which is defined to be $h_\infty \circ g_0$.

Let l_j and m_j be a longitude which lies in a tubular neighbourhood of $c_j \times \{1/2\}$ lying on a level surface along $c_j \times \{1/2\}$, and any meridian intersecting l_j at one point. Let $m_j(k)$ and $l_j(k)$ be a meridian and longitude in N_k obtained by pulling back m_j and l_j using approximate isometries. We orient them so that (l_j, m_j) determines an orientation of a torus around $c_j \times \{1/2\}$ whose normal vectors point to the inside of N_∞. Now, we consider a hyperbolic Dehn filling of N_k such that the compressing disc is attached along a curve represented by $-k[l_j(k)] + [m_j(k)]$. Since N_k converges geometrically to N_∞, we see, by passing to a subsequence, that the filling corresponding to $-k[l_j(k)] + [m_j(k)]$ is hyperbolic. We define M_k to be thus obtained geometrically finite hyperbolic 3-manifold, which is homeomorphic to $S \times (0, 1)$. We let G_k be the corresponding quasi-Fuchsian group, and $\phi_k : \pi_1(S) \to \pi_1(M_k)$ an isomorphism derived from the pull-back of g_k by an approximate isometry between N_k and M_k. By the same argument as in [2], we see that the conformal structure at infinity of M_k on the end corresponding to $S \times \{0\}$, denoted by m_k, is obtained by performing the ka_j-time (right-hand) Dehn twist around the c_j and the earthquake along $k(\mu_1^- \cup \cdots \cup \mu_s^-)$ from m_0 and that on the end corresponding to $S \times \{1\}$, denoted by n_k, by performing the $k(a_j + 1)$-Dehn twist around the c_j and the earthquake along $k(\mu_1^+ \cup \cdots \cup \mu_t^+)$. This shows that the limits in the Thurston compactification of the conformal structures m_k and n_k are $[\mu^-]$ and $[\mu^+]$ respectively, and that those of $(\tau_{c_1}^{-ka_1} \circ \cdots \circ \tau_{c_r}^{-ka_r})_*(m_k)$ and $(\tau_{c_1}^{-k(a_1+1)} \circ \cdots \circ \tau_{c_r}^{-k(a_r+1)})_*(n_k)$ are $[\mu_1^- \cup \cdots \cup \mu_s^-]$ and $[\mu_1^+ \cup \cdots \cup \mu_t^+]$ respectively. In the case when one of these latter two projective laminations is empty, the corresponding conformal structure stays in a compact set of the Teichmüller space.

By the diagonal argument, we see that $\{(G_k, \phi_k)\}$ converges algebraically to a subgroup of Γ_∞ corresponding to the covering of N_∞ associated to $(g_\infty)_*\pi_1(S)$. Thus we have obtained a sequence of quasi-Fuchsian groups $\{(G_k, \phi_k)\}$ as we wanted.

For the example which we have constructed above, if either μ^- or μ^+ consists only of $c_1, \ldots, c_r$, then $(\tau_{c_1}^{-ka_1} \circ \cdots \circ \tau_{c_r}^{-ka_r})_*(m_k)$ or $(\tau_{c_1}^{-k(a_1+1)} \circ \cdots \circ \tau_{c_r}^{-k(a_r+1)})_*(n_k)$ stays in a compact set of the Teichmüller space. We can also make it converge to a projective lamination ν^- or ν^+ not containing $c_1, \ldots, c_r$ as leaves, by composing the earthquake along $\sqrt{k}\nu^-$ or $\sqrt{k}\nu^+$.

8. NON-EXISTENCE OF EXOTIC CONVERGENCE

We shall prove Theorem 7.

Let Γ be a b-group as in the statement and $\psi : \pi_1(S) \to \Gamma$ an isomorphism giving the marking. Let $\{(G_i, \phi_i)\}$ be a sequence of quasi-Fuchsian groups converging to (Γ, ψ). What we need to show is that the conformal structures at infinity of the bottom ideal boundaries of the $M_i = \mathbb{H}^3/G_i$ are bounded in the Teichmüller space then.

Let M_∞ be a geometric limit (a subsequence) of M_i with basepoint coming from a fixed basepoint in $\mathbb{H}^3$ as usual. Let $\mathbf{M}$ be a model manifold of $(M_\infty)_0$ with a model map $f_\infty : \mathbf{M} \to (M_\infty)_0$. Let $g' : S \to \mathbf{M}$ be a standard algebraic immersion. By our assumption, there is no isolated algebraic parabolic loci in $\mathbf{M}$. This implies by Lemma 4.7 that there is no torus boundary around which g' can go. If there is an algebraic simply degenerate end below $g'(S)$, it is mapped to a simply degenerate end of $(M_\infty)_0$ which is lifted to a lower simply degenerate end of $(\mathbb{H}^3/\Gamma)_0$. This is a contradiction since Γ is a b-group. Similarly, there is no lower algebraic parabolic locus. Since g' does not go around a torus boundary component, an end closest to $g'(S)$ among those below $g'(S)$ must be algebraic. These imply that the only possible end below $g'(S)$ is a geometrically finite end corresponding to the entire $S \times \{0\}$.

The diameter of the manifold cobounded by $f_\infty \circ g'(S)$ and the lower boundary of the convex core in $(M_\infty)_0$ is finite since the manifold cobounded by $g'(S)$ and $S \times \{0\}$ in $\mathbf{M}$ has finite diameter. This cobordism in $(M_\infty)_0$ can be pulled back to $(M_i)_0$ for large i. It follows that the lower convex core of M_i converges geometrically to that of M_∞, and hence the marked hyperbolic structure on the lower boundary component of the convex core of M_i converges to that of M_∞. This shows that the lower conformal structure at infinity of M_i is bounded in the Teichmüller space as $i \to \infty$ by Sullivan's theorem (see Epstein-Marden [17]).

9. Self-bumping

In this section, we shall prove Theorem 8 and Corollary 9. For that, we shall show that for $\{qf(m_i, n_i)\}$ as in the statement of Theorem 8, there is a continuous deformation to a strong convergent sequence whose algebraic limit is a quasi-conformal deformation of Γ. This will be done by using a model manifold of $qf(m_i, n_i)$ with a special property, which we shall construct in Lemma 9.2. Let us state the existence of a deformation as a proposition.

Proposition 9.1. *We consider quasi-Fuchsian groups $qf(m_i, n_i)$ and their algebraic limit (Γ, ψ) as in Theorem 8. Let $c_1, \ldots, c_s$ be core curves of the upper parabolic loci and $c'_1, \ldots, c'_t$ be those of the lower parabolic loci on S of (Γ, ψ). Then, passing to a subsequence of $\{(m_i, n_i)\}$, there is an arc $\alpha_i : [0,1] \to QF(S)$ with the following properties. Let $(\bar{m}_i, \bar{n}_i)$ denote a point in $\mathcal{T}(S) \times \mathcal{T}(\bar{S})$ such that $qf(\bar{m}_i, \bar{n}_i) = \alpha_i(1)$.*

1. *$\alpha_i(0) = qf(m_i, n_i)$.*
2. *$\{\alpha_i(1) = qf(\bar{m}_i, \bar{n}_i)\}$ converges strongly to a quasi-conformal deformation (Γ', ψ') of (Γ, ψ) as $i \to \infty$.*
3. *The length of each of $c_1, \ldots, c_s$ with respect to $\bar{n}_i$ goes to 0 and the length of each of $c'_1, \ldots, c'_t$ with respect to $\bar{m}_i$ also goes to 0 as $i \to \infty$.*
4. *In the case when Γ is a b-group, the lower conformal structure at infinity of $\alpha_i(t)$ is constant with respect to t, for every i.*
5. *For any neighbourhood U in $AH(S)$ of the quasi-conformal deformation space $QH(\Gamma, \psi)$, there exists i_0 such that for $i > i_0$, the arc α_i is contained in U.*

9.1. **Proof of Proposition 9.1.** Set $(G_i, \phi_i) = qf(m_i, n_i)$ and $M_i = \mathbb{H}^3/G_i$. We consider the geometric limit M_∞ of M_i with basepoints coming from some fixed basepoint in $\mathbb{H}^3$. Let $\mathbf{M}_i$ be a bi-Lipschitz model of $(M_i)_0$ and $\mathbf{M}$ that of $(M_\infty)_0$ as before. Let $g' : S \to \mathbf{M}$ be a standard algebraic immersion as in Lemma 4.4. Let $E^1, \ldots, E^p$ be the algebraic simply degenerate ends of $\mathbf{M}$. We shall consider to deform $\{(G_i, \phi_i)\}$ to make all of these ends lie on $S \times \{0\} \cup S \times \{1\}$ in the new geometric limit.

We renumber $E^1, \ldots, E^p$ so that $E^1, \ldots, E^q$ are upper ends whereas $E^{q+1}, \ldots, E^p$ are lower. (It may be possible that $p = 0$ or $q = p$.) Since we assumed that Γ has no isolated parabolic loci, each of $c_1, \ldots, c_s$ is homotopic to a component of $\mathrm{Fr}\Sigma^j$ for $j = 1, \ldots, q$ and each of $c'_1, \ldots, c'_t$ is homotopic to a component of $\mathrm{Fr}\Sigma^j$ for $j = q+1, \ldots, p$. We let Σ^j be a subsurface of S such that E^j is contained in a brick of the form $\Sigma^j \times J^j$. We shall show that we can modify model manifolds

$\mathbf{M}_i$ and $\mathbf{M}$ so that there are two horizontal surfaces in a new model manifold, one containing all the upper ends $E^1, \ldots, E^q$ and the other containing all the lower ends $E^{q+1}, \ldots, E^p$.

Lemma 9.2. *There are uniform bi-Lipschitz model manifolds* $\mathbf{M}'_i$ *for* $(M_i)_0$ *and* $\mathbf{M}'$ *for* $(M_\infty)_0$*, both of which are embedded in* $S \times [0,1]$ *preserving horizontal and vertical foliations, and have the following properties.*

1. $\mathbf{M}'_i[k]$ *converges geometrically to* $\mathbf{M}'[k]$ *for every* $k \in \{0, 1, \ldots, \}$*.*
2. *There is a homeomorphism from* $\mathbf{M}$ *to* $\mathbf{M}'$ *taking algebraic loci of* $\mathbf{M}$ *to those of* $\mathbf{M}'$*. (See §4.2 for the definition of algebraic locus.)*
3. *We use the same symbol* E^j $(j = 1, \ldots, p)$ *to denote the end of* $\mathbf{M}'$ *corresponding to* E^j *of* $\mathbf{M}$*. Then,* E^j *is contained in a brick* $\bar{B}^j = \Sigma^j \times J^j$ *of* $\mathbf{M}'$ *such that* $\inf \bar{B}^1 = \cdots = \inf \bar{B}^q, \sup \bar{B}^1 = \cdots = \sup \bar{B}^q, \sup \bar{B}^{q+1} = \cdots = \sup \bar{B}^p$*, and* $\inf \bar{B}^{q+1} = \cdots = \inf \bar{B}^p$*, with* $\inf \bar{B}^1 > \sup \bar{B}^p$ *unless* $q = 0$ *or* $p = q$*.*
4. *An algebraic locus in* $\mathbf{M}'$ *can be homotoped to a horizontal surface lying between* $\sup \bar{B}^p$ *and* $\inf \bar{B}^1$*.*

Proof. For each component c of $\mathrm{Fr}\Sigma^j$ for Σ^j among $\Sigma^1, \ldots, \Sigma^q$, we consider a solid torus $V(c)$ in $S \times (0,1)$ which has the form of $A(c) \times J_c$, where $A(c)$ is an annulus with core curve c and J_c is a closed interval in $[0,1]$ such that $\inf J_c = \inf B^j$ and $\sup J_c < \sup \bar{B}^j$. Let $\bar{\mathcal{T}}^+$ be the union of all $V(c)$ for all frontier components of $\Sigma^1, \ldots, \Sigma^q$. Even if a curve c is homotopic to frontier components of two distinct Σ^j and $\Sigma^{j'}$, we take only one solid torus. In such a case, we take J_c so that $\sup J_c < \min\{\sup B^j, \sup B^{j'}\}$. Similarly, we take $\bar{\mathcal{T}}^-$ for $\Sigma^{q+1}, \ldots, \Sigma^p$.

Now for each $V(c) = A(c) \times J_c$ in $\bar{\mathcal{T}}^+$, we let $V'(c)$ be $A(c) \times [5/8, 3/4]$ in $S \times [0,1]$, and denote the union of such solid tori by $\mathcal{T}^+$. Similarly, for each $V(c)$ in $\bar{\mathcal{T}}^-$, we let $V'(c)$ be $A(c) \times [1/4, 3/8]$, and denote the union of such solid tori by $\mathcal{T}^-$. Then, we see that there is a homeomorphism from $S \times (0,1) \setminus (\bar{\mathcal{T}}^- \cup \bar{\mathcal{T}}^+)$, in which $\mathbf{M}$ is embedded, to $S \times (0,1) \setminus (\mathcal{T}^- \cup \mathcal{T}^+)$ taking a standard algebraic immersion g' to $S \times \{1/2\}$ since $\mathbf{M}$ has no torus boundary around which g' can go (Lemma 4.7) and $\bar{\mathcal{T}}^-$ lies in the lower component of $S \times [0,1] \setminus g'(S)$ whereas $\bar{\mathcal{T}}^+$ lies in the upper component.

We let a new brick manifold $\bar{\mathbf{M}}$ be the one obtained by the standard brick decomposition of $S \times [1/8, 7/8] \setminus (\mathcal{T}^- \cup \mathcal{T}^+)$. Then $\bar{\mathbf{M}}$ consists of bricks lying on five levels: the top one $S \times [3/4, 7/8]$, those touching $\bar{\mathcal{T}}^+$ along vertical boundaries, the middle one $S \times [3/8, 5/8]$, those touching $\bar{\mathcal{T}}^-$ along vertical boundaries, and the bottom one $S \times [1/8, 1/4]$. For each i, we define a labelled brick manifold $\check{\mathbf{M}}'_i$ to be the one obtained by attaching two geometrically finite bricks (i.e. boundary blocks) $S \times (0, 1/8]$ and $S \times [7/8, 1)$, one on the top and the other on the bottom to $\bar{\mathbf{M}}$. We give conformal structures m_i to the bottom and n_i to the top.

Corresponding to $\check{\mathbf{M}}'_i$, we shall construct a geometrically finite hyperbolic manifolds from M_i using the drilling theorem of Bromberg [11] and Brock-Bromberg [8]. Recall that by $f_i \circ (\rho_i^{\mathbf{M}})^{-1}$, each boundary component of $\mathcal{T}^+$ and $\mathcal{T}^-$ is mapped to the boundary of a Margulis tube in M_i. We denote the Margulis tubes in M_i corresponding to $\mathcal{T}^+$ by $V_1^i, \ldots, V_s^i$ and those corresponding to $\mathcal{T}^-$ by ${V_1^i}', \ldots, {V_t^i}'$, whose core geodesics $c_1^i, \ldots, c_s^i; {c_1^i}', \ldots, {c_t^i}'$ correspond to $\Phi_i(c_1), \ldots, \Phi_i(c_s); \Phi_i(c'_1) \ldots, \Phi_i(c'_t)$. Note that the length of each of $c_1^i, \ldots, c_s^i; {c_1^i}', \ldots, {c_t^i}'$ goes to 0 as $i \to \infty$. Moreover, for sufficiently large i, the map $f_i \circ (\rho_i^{\mathbf{M}})^{-1}$ induces a homeomorphism from

$S \times (0,1) \setminus (\bar{\mathcal{T}}^+ \cup \bar{\mathcal{T}}^-)$ to M_i. The complement of these curves $\check{M}_i = M_i \setminus (\cup_{j=1}^s c_j^i \cup \cup_{j=1}^t c_j^{i\prime})$ admits a geometrically finite hyperbolic structure with conformal structures m_i at the bottom and n_i at the top, by Thurston's uniformisation theorem. Therefore, for sufficiently large i, we can apply the drilling theorem to see that for some K independent of i, there is a K-bi-Lipschitz homeomorphism $\check{f}_i$ between $M_i \setminus (\cup_{j=1}^s V_j^i \cup \cup_{j=1}^t V_j^{i\prime})$ and $(\check{M}_i)_0$.

By the general theory which we developed in §3.4 of [35], we can decompose $\check{\mathbf{M}}_i'$ into blocks, which define a metric on $\check{\mathbf{M}}_i'$. Theorem 4.1 in the same paper shows that we have an L-bi-Lipschitz model map $f_i' : \check{\mathbf{M}}_i' \to (\check{M}_i)_0$, with L independent of i. Then, by composing $(\check{f}_i)^{-1}$ with f_i', we get a K'-bi-Lipschitz embedding of $\check{\mathbf{M}}_i'$ into M_i, with K' depending only on K and L. By filling appropriate Margulis tubes into $\check{\mathbf{M}}_i'$, we get a K''-bi-Lipschitz model manifold $\mathbf{M}_i'$ for $(M_i)_0$, with K'' independent of i, for sufficiently large i.

It remains to verify that this $\mathbf{M}_i'$ has the desired properties. Since $\mathbf{M}_i'$ has decomposition into blocks, and is a uniform bi-Lipschitz model for $(M_i)_0$, by the argument of §5 of [35], there is a labelled brick manifold $\mathbf{M}'$ which is a bi-Lipschitz model manifold of $(M_\infty)_0$ such that $\mathbf{M}_i'[k]$ converges to $\mathbf{M}'[k]$ geometrically. This shows the conditions (1) and (2). Since the geometric convergence of $\mathbf{M}_i'[k]$ to $\mathbf{M}'[k]$ preserves horizontal foliations, the bottom annuli of all the boundary components of $\mathbf{M}'$ corresponding to $\bar{\mathcal{T}}^+$ lie on the same horizontal surface $S \times \{t_1\}$, the top annuli of all the components corresponding to $\bar{\mathcal{T}}^-$ lie on the same horizontal surface $S \times \{t_2\}$, and $t_1 > t_2$, with respect to the embedding of $\mathbf{M}'$ into $S \times [0,1]$ preserving the horizontal and vertical foliations. Therefore, we have $\inf \bar{B}^1 = \cdots = \inf \bar{B}^q, \sup \bar{B}^{q+1} = \cdots = \sup \bar{B}^p$, and we can modify the embedding by making the height of these bricks sufficiently small to make the condition (3) $\sup \bar{B}^1 = \cdots = \sup \bar{B}^q, \inf \bar{B}^{q+1} = \cdots = \inf \bar{B}^p$ hold. Finally, we verify the condition (4). Since $E^1, \ldots, E^q$ are upper ends and $E^{q+1}, \ldots, E^p$ are lower ends, an algebraic locus must pass under $\bar{B}^1, \ldots, \bar{B}^q$ and above $\bar{B}^{q+1}, \ldots, \bar{B}^q$. By our assumption, there are no other algebraic ends, neither torus boundary components containing algebraic parabolic curves. Therefore, there is no obstruction to homotope an algebraic locus to a horizontal surface above $\bar{B}^{q+1}, \ldots, \bar{B}^p$ and below $\bar{B}^1, \ldots, \bar{B}^q$. $\square$

We shall use the symbol g' to denote the horizontal algebraic locus in $\mathbf{M}'$ as in (4) of the above lemma. (This is the same symbol as the standard immersion in $\mathbf{M}$, but there is no fear of confusion since we can distinguish them by model manifolds in which they are lying.)

Take s, t, s' and t' such that $B^j = \Sigma^j \times [s, t)$ for $j = 1, \ldots, q$ and $B^j = \Sigma^j \times (s', t']$ for $j = q+1, \ldots, p$. Let $\rho_i^{\mathbf{M}'}$ denote an approximate isometry between $\mathbf{M}_i'$ and $\mathbf{M}'$ which is associated to the geometric convergence of $\mathbf{M}_i'[k]$ to $\mathbf{M}'[k]$. We denote by x_i' and x_∞' basepoints in the thick parts of $\mathbf{M}_i'$ and $\mathbf{M}'$, which we used for the convergence. By our construction of $\mathbf{M}_i'$, there are bricks $B_i^j \cong \Sigma^j \times [s, u]$ of $\check{\mathbf{M}}_i$ which contains $(\rho_i^{\mathbf{M}'})^{-1}(B^j \cap B_{K_i r_i}(\mathbf{M}', x_\infty))$.

Now, we shall construct two sequences of markings on S starting from c_{m_i} and c_{n_i} respectively, and a sequence of markings on Σ^j for $j = 1, \ldots, p$, in both of which markings advance by elementary moves. Recall that $\check{\mathbf{M}}_i'$ consists of interior bricks lying on five levels and two geometrically finite bricks. Since $\check{\mathbf{M}}_i'$ is a labelled brick manifold, there are tube unions in $\check{\mathbf{M}}_i'$ which decompose it into blocks. As was shown in §3.4 in [35], each real front of every brick intersects tubes so that its complement is a disjoint union of thrice-punctured spheres.

We first consider the bottom interior brick corresponding to $S \times [1/8, 1/4]$. We denote this brick by $\bar{B}_i$. Lemma 4.4 in [35] shows that we have a 4-complete hierarchy $\check{h}(\bar{B}_i)$ on S corresponding to tube unions in $\bar{B}_i$, whose initial marking is c_{m_i}. In each annular component domain in $\check{h}(\bar{B}_i)$ except for those corresponding to tubes intersecting the upper front of $\bar{B}_i$, we can put a tight geodesic, which is uniquely determined. The length of such a geodesic determines the $\omega_{\mathbf{M}_i}$ of the Margulis tube which was filled in the corresponding torus boundary of $\check{\mathbf{M}}'_i[0]$. For each annular component domain corresponding to a tube intersecting the upper front, we put a geodesic of length 0 at this stage, for the terminal markings for such geodesics are not determined if we look only at $\bar{B}_i$. We denote by $h(\bar{B}_i)$ the hierarchy obtained by adding such annular geodesics to $\check{h}(\bar{B}_i)$. A resolution $\tau(\bar{B}_i) = \{\tau(\bar{B}_i)_k\}$ of $h(\bar{B}_i)$ gives rise to a sequence of split level surfaces starting from the one lying on the lower front and ending at the one lying on the upper front. On the other hand, forward steps in the resolution $\tau(\bar{B}_i)$ corresponds to elementary moves of markings which can be assumed to be clean. (See Minsky [29].) Next we consider the top interior brick, which corresponds to $S \times [3/4, 7/8]$, and we denote by $\hat{B}_i$. Similarly to the case of $\bar{B}_i$, we have a hierarchy $h(\hat{B}_i)$. Reversing the order of slices of this hierarchy, we get a resolution, which we denote by $\tau(\hat{B}_i) = \{\tau(\hat{B}_i)_k\}$, giving rise to split level surfaces starting from the one on the upper front and ending at the one on the lower front, and a sequence of clean markings on S advancing by elementary moves. Since $\mathbf{M}'_i$ is obtained from $\check{\mathbf{M}}'_i$ by filling Margulis tubes, the split level surfaces as above can be also regarded as lying in $\mathbf{M}'_i$.

Next we consider a brick B_i^j for $j = q+1, \ldots, p$. Again, we have a complete hierarchy $h(B_i^j)$ supported on Σ^j corresponding to the decomposition of B_i^j into blocks and filled-in Margulis tubes. We can take a resolution $\tau(B_i^j) = \{\tau(B_i^j)_k\}$ starting from the restriction of the last slice of $\tau(\bar{B}_i)$ to Σ^j. Similarly, for each brick B_i^j for $j = 1, \ldots, p$, we have a complete hierarchy $h(B_i^j)$. We reverse the order of slices in this case, and consider a resolution $\tau(B_i^j) = \{\tau(B_i^j)_k\}$ starting from the restriction of the last slice of $\tau(\hat{B}_i)$.

For each $n \in \mathbb{N}$, we consider the n-th slice $\tau(B_i^j)_{-n}$ counting from the last one of each $\tau(B_i^j)$ for $j = q+1, \ldots, p$. Corresponding to the slice $\tau(B_i^j)_{-n}$, we have a split level surface $S(B_i^j)(n)$ embedded in B_i^j. Taking the union of all $S(B_i^j)(n)$ and the thrice-punctured spheres lying on $\partial_+ \bar{B}_i \setminus (\cup_{j=p+1}^q B_i^j)$, we get a split level surface $S_i^-(n)$. We construct an *extended level surface* $\hat{S}_i^-(n)$ as follows. Let $\mathbf{T}_-$ union of Margulis tubes intersecting $S_i^-(n)$. Each torus T in $\partial \mathbf{T}_-$ is split into two annuli by cutting along $T \cap S_i^-(n)$, which we call upper annulus and lower annulus depending on their locations. We paste the upper one to $S_i^-(n)$ for each T and get a surface homeomorphic to S, which we define to be $\hat{S}_i^-(n)$. We also regard a union of slices, taken one from each $\tau(B_i^j)$ $(j = q+1, \ldots, p)$, as a marking on the entire S by defining its restriction to $S \setminus \cup_{j=q+1}^p \Sigma^j$ to be the marking defined by the last slice of $\tau(\bar{B}_i)$, and setting a transversal of a component c of $\mathrm{Fr}\Sigma^j$ to be the one determined by the first vertex of a geodesic supported on an annular neighbourhood $A(c)$ of c, which is uniquely determined by the Margulis tube of $\mathbf{M}'_i$

corresponding to c. We can consider the same construction for B_i^j with $j = 1, \ldots, q$, and get a split level surface $S_i^+(n)$ and an extended split level surface $\hat{S}_i^+(n)$, this time using lower annuli. Also, we can regard a union of slices taken one from each $\tau(B_i^j)\,(j = 1, \ldots, q)$ as a marking on the entire S in the same way, by setting a transversal of each component of $\mathrm{Fr}\Sigma_j$ to be the last vertex this time.

Recall that in the construction of model manifolds, Minsky defined the initial and terminal markings as the shortest markings for the conformal structures at infinity. We consider a correspondence in the opposite direction. We can choose some positive constant δ_0 such that for any clean marking, there is a marked conformal structure on S in which all the curves (both base curves and transversals) of the marking have hyperbolic lengths greater than δ_0. (The existence of such constant is easy to see since there are only finitely many configurations of clean markings up to homeomorphisms of S.) For each marking μ, we define the marked conformal structure $m(\mu)$ to be one for which a clean marking μ' compatible with μ is a shortest marking and such that every curve of μ' has hyperbolic length greater than δ_0. Although there are more than one such structures, we just choose any one. Then there is a universal constant K depending only on δ_0 (and S) such that if μ' is obtained from μ by one step in the resolutions $\tau(\bar{B}_i)$ or $\tau(\hat{B}_i)$ or $\tau(B_i^j)$, which corresponds to an elementary move of markings on S or Σ_j, then the Teichmüller distance between $m(\mu)$ and $m(\mu')$ is bounded by K, whatever choices of $m(\mu)$ and $m(\mu')$ we make.

Now, we shall consider two sequences of markings. The first one is obtained by combining a sequence of markings corresponding to $\tau(\bar{B}_i)$ with those corresponding to the $\tau(B_i^j)\,(j = q+1, \ldots, p)$. By our definition of markings corresponding to slices in $\tau(B_i^j)$, if we choose first slice from every $\tau(B_i^j)$, the corresponding marking coincides with the one corresponding to the last slice of $\tau(\bar{B}_i)$, where vertices on annular geodesics are regarded as the first ones. Therefore after the sequence of markings for $\tau(\bar{B}_i)$, we can append the one obtained by advancing slices in the $\tau(B_i^j)\,(j = q+1, \ldots, p)$, so that we proceed at each step by advancing a slice in $\tau(B_i^j)$ which is farthest from the goal, i.e. the n-th slice counted from the last one, up to the point where all the slices are the n-th counting from the last one. We denote thus obtained sequence of markings by $\mu^-(i,n) = \{\mu_k^-(i,n)\}$. In the same way, we define a sequence of markings obtained by combining one corresponding to $\tau(\hat{B}_i)$ with those corresponding to $\tau(B_i^j)\,(j = 1, \ldots, q)$. We denote this sequence by $\mu^+(i,n) = \{\mu_l^+(i,n)\}$. To simplify the notation, we denote the last markings in $\mu^-(i,n)$ and $\mu^+(i,n)$ by $\mu_\infty^-(i,n)$ and $\mu_\infty^+(i,n)$ respectively.

For these sequences, we can construct arcs in the Teichmüller space as follows. Starting from $\mu_1^-(i,n)$, which is a shortest marking for m_i, we consider for each step $\mu_k^-(i,n) \to \mu_{k+1}^-(i,n)$ in $\mu^-(i,n)$, a Teichmüller geodesic arc connecting $m(\mu_k^-(i,n))$ with $m(\mu_{k+1}^-(i,n))$, and then construct a broken geodesic arc $\alpha^-(i,n)$ connecting $m(\mu_1^-(i,n))$ to $m(\mu_\infty^-(i,n))$ by joining them. Both $m(\mu_1^-(i,n))$ and m_i have $\mu_1^-(i,n)$ as a shortest marking, but the hyperbolic lengths of base curves of $\mu_1^-(i,n)$ may be different in m_i and in $m(\mu_1^-(i,n))$. We can connect m_i with $m(\mu_1^-(i,n))$ by a Teichmüller quasi-geodesic so that $\mathrm{base}(\mu_1^-(i,n))$ remains a shortest pants decomposition throughout the points on the geodesic. (The quasi-geodesic constant depends only on S.) We define $\bar{\alpha}^-(i,n)$ to be a broken quasi-geodesic arc obtained by joining this quasi-geodesic with $\alpha^-(i,n)$. In the same way, we construct a broken quasi-geodesic arc $\bar\alpha^+(i,n)$ connecting n_i with $m(\mu_\infty^+(i,n))$. In the case when either lower or upper algebraic simply degenerate ends do not exist, we define the corresponding $\bar\alpha^-(i,n)$ or $\bar\alpha^+(i,n)$ to be a constant map.

For any n, if we take a sufficiently large i, the component of $(\rho_i^{\mathbf{M}'})^{-1}(\mathbf{M}' \cap B_{K_i r_i}(\mathbf{M}', x_\infty))$ containing $(\rho_i^{\mathbf{M}'})^{-1}(g'(S))$ contains all $\hat S_i^-(k)$ and $\hat S_i^+(k)$ with $k \leq n$, since the distance between B_i^j and $(\rho_i^{\mathbf{M}'})^{-1}(g'(S))$ is uniformly bounded, and so are the diameters of extended level surfaces. Now, for each i, let $\mathbf{n}_i$ be the largest number such that both $S_i^-(k)$ and $S_i^+(k)$ with all $k \leq \mathbf{n}_i$ are contained in the component of $(\rho_i^{\mathbf{M}'})^{-1}(\mathbf{M}' \cap B_{K_i r_i}(\mathbf{M}', x_\infty))$ containing $(\rho_i^{\mathbf{M}'})^{-1}(g'(S))$ and are homotopic to $(\rho_i^{\mathbf{M}'})^{-1}(g'(S))$. By the above observation, we have $\mathbf{n}_i \to \infty$ as $i \to \infty$. Let $\alpha_i^\pm : [0, k_i^\pm] \to \mathcal{T}(S)$ be broken quasi-geodesic arcs $\bar\alpha^\pm(i, \mathbf{n}_i)$ connecting $m(\mu_\infty^\pm(i,\mathbf{n}_i))$ with m_i, n_i which are constructed as above by joining Teichmüller geodesics and one quasi-geodesic, setting n above to be $\mathbf{n}_i$. We parametrise $\alpha_i^\pm$ so that the integral points in $[0, k_i^\pm]$ correspond to the endpoints of the Teichmüller geodesics. We define $\beta_i : [0, \bar k_i] \to QF(S)$ by setting $\beta_i(t)$ to be $qf(\alpha_i^-(t), \alpha_i^+(t))$, where $\bar k_i = \max\{k_i^+, k_i^-\}$ and we assume the arcs $\alpha_i^\pm$ stay at the endpoint after t gets out of the domain.

Claim 9.3. A sequence of quasi-Fuchsian group $\{qf(m(\mu_\infty^-(i,\mathbf{n}_i)), m(\mu_\infty^+(i,\mathbf{n}_i))\}$ converges strongly to a quasi-conformal deformation of (Γ, ψ) after passing to a subsequence.

Proof. By our definition of the function m and the argument in the proof of Lemma 9.2, a uniformly bi-Lipschitz model manifold for the quasi-Fuchsian group $qf(m(\mu_\infty^-(i,\mathbf{n}_i)), m(\mu_\infty^+(i,\mathbf{n}_i)))$, which we denote by $\mathbf{M}'(\mathbf{n}_i)$, can be obtained from the submanifold of $\mathbf{M}'_i[0]$ cobounded by $S_i^-(\mathbf{n}_i)$ and $S_i^+(\mathbf{n}_i)$ by pasting boundary blocks corresponding to $m(\mu_\infty^-(i,\mathbf{n}_i))$ and $m(\mu_\infty^+(i,\mathbf{n}_i))$ respectively and filling Margulis tubes. This model manifold contains $(\rho_i^{\mathbf{M}'})^{-1} \circ g'(S)$. It follows that for a fixed generator system of $\pi_1(S)$ with base point on $(\rho_i^{\mathbf{M}'})^{-1} \circ g'(S)$, the length of the shortest curve in $\mathbf{M}'(\mathbf{n}_i)$ representing each generator is bounded as $i \to \infty$, and hence that $qf(m(\mu_\infty^-(i,\mathbf{n}_i)), m(\mu_\infty^+(i,\mathbf{n}_i)))$ converges algebraically after passing to a subsequence. Let (Γ', ψ') be the algebraic limit, and denote $\mathbb{H}^3/\Gamma'$ by $M_{\Gamma'}$.

The geometric limit $\mathbf{M}'(\mathbf{n}_\infty)$ of the complement of boundary blocks in $\mathbf{M}'(\mathbf{n}_i)$ is embedded in $\mathbf{M}'$ as a submanifold, by our definition of $\mathbf{M}'(\mathbf{n}_i)$. For each $j = 1, \ldots, q$, the intersection of $\rho_i^{\mathbf{M}'}(S_i^+(\mathbf{n}_i))$ with B^j goes deeper and deeper into B^j to the direction of the end E_j as $i \to \infty$ since $\mathbf{n}_i \to \infty$. The same holds for $\rho_i^{\mathbf{M}'}(S_i^-(\mathbf{n}_i)) \cap B^j$ for $j = q+1, \ldots p$. Therefore the entire B^j is contained in $\mathbf{M}'(\mathbf{n}_\infty)$ for every $j = 1, \ldots, p$.

Let $\mathbf{V}_i^k$ $(k = 1, \ldots, s)$ be the Margulis tube in $\mathbf{M}'_i$ corresponding to V_i^k in M_i, and let F_i be a component of $\hat S_i^+(\mathbf{n}_i) \setminus (\cup_{j=1}^q B_i^j \cup \cup_{k=1}^s \mathbf{V}_i^k)$. The boundary of F_i lies on $\cup_{k=1}^s \partial \mathbf{V}_i^k$, which converges geometrically to a union of annular boundary components of $\mathbf{M}'$. Since each component of $F_i \cap \cup_{k=1}^s \partial \mathbf{V}_i^k$ does not go into B_i^j, its image under $\rho_i^{\mathbf{M}'}$ stays in a compact subset of the annular boundary component. Furthermore, there is a positive lower bound for the injectivity radii of the points on F_i since its geometric limit cannot intersect a parabolic locus of $\mathbf{M}'$ other than those in $\mathcal{T}$ by the assumption that there is no isolated algebraic parabolic locus. These imply that F_i converge geometrically to a surface F_∞ which is homeomorphic to F_i

for large i. The same holds for each component of $\hat{S}_i^-(\mathbf{n}_i) \setminus (\cup_{j=q+1}^p B_i^j \cup \cup_{k=1}^t \mathbf{V}_i^k)$, where $\mathbf{V}_i^k$ is the Margulis tube in $\mathbf{M}_i$ corresponding to $V_i^{k\prime}$. Let $F_\infty^1, \ldots, F_\infty^r$ be such geometric limits for the components of $\hat{S}_i^+(\mathbf{n}_i) \setminus (\cup_{j=1}^q B_i^j \cup \cup_{k=1}^s \mathbf{V}_i^k)$ and $\hat{S}_i^-(\mathbf{n}_i) \setminus (\cup_{j=q+1}^p B_I^j \cup \cup_{k=1}^t \mathbf{V}_i^k)$. Then, $\mathbf{M}'(\mathbf{n}_\infty)$ is obtained by cutting $\mathbf{M}'$ along $\cup_{j=1}^r F_\infty^j$, has simply degenerate ends $E_1, \ldots, E_p$, and is homotopy equivalent to S in particular. A model manifold of the geometric limit of $m(\mu_\infty^-(i, \mathbf{n}_i)), m(\mu_\infty^+(i, \mathbf{n}_i)))$ is obtained by pasting boundary blocks homeomorphic to $F_\infty^1 \times [u, 1), \ldots, F_\infty^r \times [u, 1)$ to $\mathbf{M}'(\mathbf{n}_\infty)$ along $F_\infty^1, \ldots, F_\infty^r$, and hence is homeomorphic to $S \times (0, 1)$. This shows that the geometric limit has fundamental group isomorphic to $\pi_1(S)$, and hence that the convergence is strong. The model manifold shows that the ends of $M_{\Gamma'}$ consists of simply degenerate ends corresponding to $E_1, \ldots, E_p$ and geometrically finite ends and that every parabolic locus touches one of $E_1, \ldots, E_p$. Since the ending laminations of $E_1, \ldots, E_p$ are the same as those of the corresponding ends of $M' = \mathbb{H}^3/\Gamma$, by the ending lamination theorem due to Brock-Canary-Minsky [10], we see that (Γ', ψ') is a quasi-conformal deformation of (Γ, ψ). $\square$

Claim 9.4. For any sequence $\{t_i \in [0, \bar{k}_i]\}$, the sequence $\{\beta_i(t_i) \in QF(S)\}$ converges algebraically to a quasi-conformal deformation of (Γ, ψ).

Proof. Recall that $\beta_i(t_i) = qf(\alpha_i^-(t_i), \alpha_i^+(t_i))$, and that α^- and α^+ are broken quasi-geodesic arcs consisting of Teichmüller geodesics with bounded lengths except for the first quasi-geodesics which may be long. We first assume that neither $\alpha_i^-(t_i)$ nor $\alpha^+(t_i)$ lies on the first quasi-geodesics. In this case, since $\alpha_i^-(t_i)$ and $\alpha^+(t_i)$ lie on Teichmüller geodesics with bounded length, we have only to consider the case when both $\alpha^+(t_i)$ and $\alpha_i^-(t_i)$ are endpoints of Teichmüller geodesic arcs constituting α^- and α^+, i.e. the case when t_i is an integer. The marking $\alpha^-(t_i)$ corresponds to either a slice in $\tau(\bar{B}_i)$ or a union of slices, taken one from each of $\tau(B_i^j)\,(j = q+1, \ldots, p)$. This corresponds in turn to an extended level surface $\hat{S}_i^-(t_i)$. Similarly, we have an extended level surface $\hat{S}_i^+(t_i)$ from $\alpha^+(t_i)$. Then, we can see that a uniform bi-Lipschitz model manifold $\mathbf{M}'(\beta_i(t_i))$ for $\beta_i(t_i)$ is obtained from the submanifold of $\mathbf{M}_i'$ cobounded by $S_i^-(t_i)$ and $S_i^+(t_i)$ by pasting boundary blocks and filling Margulis tubes by the argument of Lemma 9.2. Then by the same argument as in the previous claim, we see that $\{\beta_i(t_i)\}$ converges algebraically after passing to a subsequence, and the geometric limit $\mathbf{M}_\infty'(\beta)$ of $\mathbf{M}'(\beta_i(t_i))$ contains $B^1, \ldots, B^p$. Since the interior blocks of $\mathbf{M}_\infty'(\beta)$ lies in $\mathbf{M}'$, the ends of the algebraic limit other than those corresponding to $E_1, \ldots, E_p$ are geometrically finite and there are no extra parabolic loci. This implies that the algebraic limit is a quasi-conformal deformation of (Γ, ψ) as in the previous claim.

Next suppose that $\alpha^+(t_i)$ lies in the first quasi-geodesic. Then all the interior blocks of $\mathbf{M}_i'$ above $(\rho_i^{\mathbf{M}'})^{-1} \circ g'(S)$ lie also in a model manifold $\mathbf{M}'(\beta(t_i))$ for $\beta(t_i)$ defined in the same way as above. Therefore, the algebraic ends of $\mathbf{M}_i'$ lie also in the model manifold $\mathbf{M}'(\beta(t_i))$. The argument for showing that there is no extra parabolic loci works also in this case. We can argue in the same way also in the case when $\alpha^-(t_i)$ lies (or both $\alpha^-(t_i)$ and $\alpha^+(t_i)$ lie) in the first geodesic. $\square$

Now, we shall complete the proof of Proposition 9.1 by setting $\alpha_i(t) = \beta_i(\bar{k}_i t)$ for β_i defined above and showing thus constructed arc α_i satisfies the conditions in the statement. The conditions (1) and (2) have already been shown. Let us show (3). By our construction, the model manifold $\mathbf{M}_i'(\beta(1))$ has Margulis tubes $\mathbf{V}_1^i, \ldots, \mathbf{V}_s^i$

and $\mathbf{V}_1^{i\,\prime}, \dots, \mathbf{V}_t^{i\prime}$ with core curves corresponding to $c_1^i, \dots, c_s^i$ and $c_1^{i\,\prime}, \dots, c_t^{i\prime}$. Because of the existence of the bricks B_i^j which supports γ_i^j with length going to ∞, for each tube V among $\mathbf{V}_1^i, \dots, \mathbf{V}_s^i; \mathbf{V}_1^{i\,\prime}, \dots, \mathbf{V}_t^{i\prime}$, we see that $\Im\omega_{\mathbf{M}_i(\beta_i(0))}(V)$ goes to ∞. Since $\mathbf{V}_1^i, \dots, \mathbf{V}_s^i$ are also attached to the upper boundary block and $\mathbf{V}_1^{i\,\prime}, \dots, \mathbf{V}_t^{i\prime}$ to the lower boundary block and the geometric limit coincides the algebraic limit, this is possible only when the upper boundary block split along the curves corresponding to $c_1^i, \dots, c_n^i$ and the lower one along curves corresponding to $c_1^{i\,\prime}, \dots c_t^{i\prime}$ in the geometric limit. This means that the length of each of $c_1^i, \dots, c_s^i$ with respect to n_i' and that of each of $c_1^{i\,\prime}, \dots, c_t^{i\prime}$ with respect to m_i' goes to 0.

Next we shall show the condition (4). In the case when Γ is a b-group, there is no lower algebraic simply degenerate ends for $\mathbf{M}'$. By our definition of β_i, in this case the lower conformal structure $\alpha_i^-(t)$ is the same as m_0 for every t.

Finally, we shall verify the condition (5). Suppose, seeking a contradiction, that the condition (5) does not hold. Then, there exist a neighbourhood U of $QH(\Gamma, \psi)$ and $t_i \in [0, k_i]$ such that $\beta_i(t_i)$ stays outside U for every i after passing to a subsequence. Now, we apply Claim 9.4 to see that $\beta(t_i)$ converges to a point in $QH(\Gamma, \psi)$ after passing to a subsequence. This is a contradiction. Thus we have completed the proof of Proposition 9.1.

9.2. **Proofs of Theorem 8 and Corollaries 9, 10.**

Proof of Theorem 8. Having proved Proposition 9.1, to prove Theorem 8, it remains to show that two sequences strongly converging to groups in the quasi-conformal deformation space of (Γ, ψ) as constructed in the proof of Proposition 9.1 can be joined by arcs in small neighbourhoods of the deformation space, fixing the conformal structure at bottom when Γ is a b-group.

Let $\{(G_i, \phi_i)\}$ and $\{(H_i, \varphi_i)\}$ be two sequences of quasi-Fuchsian groups both of which converge algebraically to quasi-conformal deformations of (Γ, ψ). Let $\mathbf{M}_i'$ and $\mathbf{N}_i'$ be model manifolds for $\mathbb{H}^3/G_i$ and $\mathbb{H}^3/H_i$ constructed as in Lemma 9.2, converging geometrically to model manifolds $\mathbf{M}'$ and $\mathbf{N}'$ for the geometric limits of $\{G_i\}$ and $\{H_i\}$ respectively. Since the algebraic limits of $\{(G_i, \phi_i)\}$ and $\{(H_i, \varphi_i)\}$ are quasi-conformally equivalent, $\mathbf{M}'$ and $\mathbf{N}'$ have the same number of algebraic simply degenerate ends with the same ending laminations $\lambda_1, \dots, \lambda_p$. As in Proposition 9.1, we renumber them so that those having $\lambda_1, \dots, \lambda_q$ as ending laminations are upper whereas the rest are lower. In particular, we can assume that the union of the boundary components $\mathcal{T}$ touching these ends, which was defined in the proof of Proposition 9.1, is the same for $\mathbf{M}'$ and $\mathbf{N}'$ as open annuli in $S \times [0, 1]$.

Let $\{(G_i', \phi_i') = qf(\bar{m}_i, \bar{n}_i)\}$ and $\{(H_i', \varphi_i') = qf(\bar{\mu}_i, \bar{\nu}_i)\}$ be two strongly convergent sequences as constructed in Proposition 9.1 for two sequences $\{(G_i, \phi_i)\}$ and $\{(H_i, \varphi_i)\}$. Recall that in the construction of such a sequence in Proposition 9.1, we took a number $\mathbf{n}_i$. Note that the construction works if we take a number smaller than $\mathbf{n}_i$ for each i provided that the number goes to ∞. Therefore, we can let the number $\mathbf{n}_i$ be common to both G_i' and H_i'. Let $\mathbf{M}'(\mathbf{n}_i)$ and $\mathbf{N}'(\mathbf{n}_i)$ be model manifolds for them as in the proof of the proposition. Then both $\mathbf{M}'(\mathbf{n}_i)$ and $\mathbf{N}'(\mathbf{n}_i)$, regarded as embedded in $S \times [0, 1]$, have the following properties. There are unions of Margulis tubes $\mathbf{V}_i$ and $\mathbf{V}_i'$ coming from $\mathcal{T}$ in $\mathbf{M}'(\mathbf{n}_i)$ and $\mathbf{N}'(\mathbf{n}_i)$ respectively, which can be assumed to correspond to the same union of solid tori in $S \times [0, 1]$. As in the proof of Proposition 9.1, the complements $\mathbf{M}'(\mathbf{n}_i) \setminus \mathbf{V}_i$ and $\mathbf{N}'(\mathbf{n}_i) \setminus \mathbf{V}_i'$

have decompositions into bricks among which there are ${B_i^j}' = \Sigma^j \times {J_i^j}'$ in $\mathbf{M}'(\mathbf{n}_i)$ and ${B_i^j}'' = \Sigma^j \times {J_i^j}''$ in $\mathbf{N}'(\mathbf{n}_i)$ on the same side of the preimages of the standard algebraic immersions. The bricks ${B_i^j}'$ and ${B_i^j}''$ contain tube unions corresponding to geodesics ${\gamma_i^j}'$ and ${\gamma_i^j}''$ supported on Σ^j whose lengths go to ∞. Furthermore, for each of ${\gamma_i^j}'$ and ${\gamma_i^j}''$, one of the endpoints stays in a compact set and the other endpoint (which we denote by ${b_i^j}'$ for ${\gamma_i^j}'$ and ${b_i^j}''$ for ${\gamma_i^j}''$) goes to the ending lamination λ_j as $i \to \infty$. Also, the tube unions put in ${B_i^j}'$ and ${B_i^j}''$ induce hierarchies ${h_i^j}'$ and ${h_i^j}''$ on Σ^j with main geodesics ${\gamma_i^j}'$ and ${\gamma_i^j}''$ respectively.

In the following, we only consider the case when the end of $\mathbf{M}'$ (hence also that of $\mathbf{N}'$) having λ_j as the ending lamination is an upper end, i.e. $j = 1, \dots q$. The case when it is an lower end can be dealt with just by turning everything upside down as usual. Let ${\mu_\infty^+}'(i, \mathbf{n}_i)$ be a sequence of markings which we constructed as in the proof of Proposition 9.1 for $\mathbf{N}'$, corresponding to $\mu^+(i, \mathbf{n}_i)$ there for $\mathbf{M}'$. In the construction of $\mathbf{M}'(\mathbf{n}_i)$ and $\mathbf{N}'(\mathbf{n}_i)$ in the proof of Proposition 9.1, the last slices of ${h_i^j}'$ and ${h_i^j}''$ correspond to the restrictions of the last terms $\mu_\infty^+(i, \mathbf{n}_i)$ and ${\mu_\infty^+}'(i, \mathbf{n}_i)$ of the sequences of markings $\mu^+(i, \mathbf{n}_i)$ and ${\mu^+}'(i, \mathbf{n}_i)$.

Since the length of the frontier of Σ^j goes to 0 with respect to both $\bar{n}_i$ and $\bar{\nu}_i$, we can assume that the length of each component of Σ^j with respect to $\bar{n}_i$ is equal to that with respect to $\bar{\nu}_i$ without changing the algebraic limit and the structure of the model manifolds except for the boundary blocks.

Now, we connect the endpoints ${b_i^j}'$ and ${b_i^j}''$ by a tight sequence $\gamma_i = \{c_1^i, \dots, c_{u_i}^i\}$ in $\mathcal{CC}(\Sigma_i^j)$. By the hyperbolicity of $\mathcal{CC}(\Sigma_i^j)$, for every integer s_i between 1 and u_i, the simplex $c_{s_i}^i$ also converges to the lamination λ_j as $i \to \infty$. By letting $\mu_\infty^+(i, \mathbf{n}_i)$ and ${\mu_\infty^+}'(i, \mathbf{n}_i)$ be the initial and terminal markings respectively, we can regard γ_i as a tight geodesic, and there is a hierarchy $h(\gamma_i)$ on Σ_j which has γ_i as its main geodesic. Considering a resolution of this hierarchy $h(\gamma_i)$, we can connect $\mu_\infty^+(i, \mathbf{n}_i)$ with ${\mu_\infty^+}'(i, \mathbf{n}_i)$ by elementary moves of markings, and correspondingly $\bar{n}_i$ with $\bar{n}_i|(S \setminus \Sigma^j) \cup \bar{\nu}_i|\Sigma^j$ by a piecewise Teichmüller geodesic arc $\delta_i : [0, w_i] \to \mathcal{T}(S)$. Since every $c_{s_i}^i$ converges to λ_j and the structure of $\mathbf{M}_i'(\mathbf{n}_i)$ outside B^j is unchanged, we see that $qf(\bar{m}_i, \delta_i(t_i))$ converges to (Γ, ψ) strongly. By the same argument as in the proof of Proposition 9.1, we see that for any neighbourhood U of $QH(\Gamma, \psi)$, the arc $qf(\bar{m}_i, \delta_i[0, w_i])$ is contained in U for large i.

We repeat the same procedure for each $j = 1, \dots, p$. Then, we get an arc α_i' connecting $qf(\bar{m}_i, \bar{n}_i)$ and $qf(\bar{m}_i|(S \setminus \cup_{j=q+1}^p \Sigma^j) \cup \bar{\mu}_i| \cup_{j=q+1}^p \Sigma_i^j, \bar{n}_i|(S \setminus \cup_{j=1}^q \Sigma^j) \cup \bar{\nu}_i| \cup_{j=1}^p \Sigma^j)$ such that for any neighbourhood U of $QH(\Gamma, \psi)$, the arc α_i' is contained in U for sufficiently large i. Since all of the $\bar{m}_i|(S \setminus \cup_{j=q+1}^p \Sigma^j)$, the $\bar{\mu}_i|(S \setminus \cup_{j=q+1}^p \Sigma^j)$, $\bar{n}_i|(S \setminus \cup_{j=1}^p \Sigma_i^j)$, and $\bar{\nu}_i|(S \setminus \cup_{j=1}^p \Sigma^j)$ are bounded in the Teichmüller spaces with free boundary, and the lengths of the boundary components are the same for $\bar{m}_i$ and $\bar{\mu}_i$ and for $\bar{n}_i$ and $\bar{\nu}_i$, we can deform $qf(\bar{m}_i|(S \setminus \cup_{j=q+1}^p \Sigma^j) \cup \bar{\mu}_i| \cup_{j=q+1}^p \Sigma^j, \bar{n}_i|(S \setminus \cup_{j=1}^q \Sigma^j) \cup \bar{\nu}_i| \cup_{j=1}^p \Sigma_i^j)$ to $qf(\bar{\mu}_i, \bar{\nu}_i)$ by a uniformly bounded quasi-conformal deformation. Thus, we have shown that we can connect $(G_i', \phi_i') = qf(\bar{m}_i, \bar{n}_i)$ with $(H_i', \psi_i') = qf(\bar{\mu}_i, \bar{\nu}_i)$ with an arc α_i in $QF(S)$ such that for any neighbourhood U of $QH(\Gamma, \psi)$, the arc α_i is contained in U large i. On the other hand, by our definition of $(\bar{m}_i, \bar{n}_i)$ and $(\bar{\mu}_i, \bar{\nu}_i)$, there are arcs with such a property connecting

(G_i, ϕ_i) with (G_i', ϕ_i') and (H_i, ψ_i) with (H_i', ψ_i'). Therefore, connecting these three arcs, we get an arc as we wanted.

In the case when Γ is a b-group, by Theorem 7, the lower conformal structures at infinity of both (G_i, ϕ_i) and (H_i, ψ_i) converge to m_0. Therefore, we can construct an arc as above keeping the lower conformal structures in an arbitrarily small neighbourhood of m_0 for large i. This shows the second paragraph of our theorem. □

Corollary 9 follows easily from this as follows.

Proof of Corollary 9. Suppose that any small neighbourhood of (Γ, ψ) intersects more than one component of $QF(S)$. Then there are sequences $\{qf(m_i, n_i)\}$ and $\{qf(\hat{m}_i, \hat{n}_i)\}$ both converging to (Γ, ψ) such that $qf(m_i, n_i)$ and $qf(\hat{m}_i, \hat{n}_i)$ belong to different component of $U \cap QF(S)$ for every small neighbourhood U of (Γ, ψ) in $QF(S)$. Applying Theorem 8, we see that $qf(m_i, n_i)$ and $qf(\hat{m}_i, \hat{n}_i)$ must be connected in a small neighbourhood of $QH(\Gamma, \psi)$. In the case when every component of Ω_Γ/Γ is a thrice-punctured sphere, this is a contradiction since $QH(\Gamma, \psi)$ consists of only (Γ, ψ) then.

In the case when there is a component of Ω_Γ/Γ which is homeomorphic to S, the Kleinian group Γ is a b-group. Then the second paragraph of Theorem 8 shows that we can connect $qf(m_i, n_i)$ to $qf(\hat{m}_i, \hat{n}_i)$ keeping the lower conformal structure within a small neighbourhood. This means that they can be connected in a small neighbourhood of (Γ, ψ) in $QF(S)$. This again is a contradiction. □

To get Corollary 10, we need to review the argument of the proof of Theorem 8.

Proof of Corollary 10. In the proof of Theorem 8, we used the assumption that Γ has no isolated parabolic loci in two places, first to show the standard immersion g' can be isotoped to a horizontal embedding, and secondly in the proofs of Claims 9.3 and 9.4 to show that the limit is a quasi-conformal deformation of (Γ, ψ). We shall show how to modify the argument in the latter part first.

In the proofs of the claims, we used the fact that all the parabolic loci of the algebraic limit Γ' of the new sequence touch simply degenerate ends, hence the parabolic loci of Γ' and Γ are the same. In our settings now, if we do the same construction, this is not the case any more. To preserve the parabolic loci throughout the modification of quasi-Fuchsian groups, we consider to modify the model manifolds $\mathbf{M}'$ and $\mathbf{M}_i'$ constructed in Lemma 9.2 as follows.

Let $c_1, \ldots, c_u$ be core curves of the isolated parabolic loci of Γ. We renumber them so that $c_1, \ldots, c_v$ are upper and $c_{v+1}, \ldots, v_u$ are lower. These curves correspond to algebraic parabolic curves in the original model manifold $\mathbf{M}$ lying on the boundary components. For each of them we set $V(c_j) = A(c_j) \times [3/4, 7/8]$ for $j = 1, \ldots, v$ and $V(c_j) = A(c_j) \times [1/8, 1/4]$ for $j = v+1, \ldots, u$. We define $\mathcal{U}^+$ to be $\cup_{j=1}^{v} V(c_j)$ and $\mathcal{U}^-$ to be $\cup_{j=v+1}^{u} V(c_j)$. We then define $\bar{M}$ to be $S \times [1/8, 7/8] \setminus (\mathcal{T}^- \cup \mathcal{T}^+ \cup \mathcal{U}^- \cup \mathcal{U}^+)$. This new $\bar{M}$ also have standard brick decomposition having five levels. Still, the bottom and top levels are changed: the bottom level consists of disjoint union of the $\Sigma \times [1/8, 1/4]$ for the components Σ of $S \setminus \cup_{j=v+1}^{u} A(c_j)$, and the top level consists of the $\Sigma \times [3/4, 7/8]$ for the components Σ of $S \setminus \cup_{j=1}^{v} A(c_j)$. By the same construction as in the proof of Lemma 9.2, we can construct model manifolds $\mathbf{M}_i'$.

This modification affects the construction of resolutions $\tau(\bar{B}_i)$ and $\tau(\hat{B}_i)$. In the present situation, $\bar{B}_i$ is a disjoint union of bricks of the form $B_1^- = \Sigma_1^- \times [1/8, 1/4], \ldots, B_w^- = \Sigma_w^- \times [1/8, 1/4]$, where $\Sigma_1^-, \ldots, \Sigma_w^-$ are the components of $S \setminus \cup_{j=v+1}^u A(c_j)$. Similarly, $\hat{B}_i$ is a disjoint union of bricks of the form $B_1^- = \Sigma_1^+ \times [3/4, 7/8], \ldots, B_y^- = \Sigma_y^+ \times [3/4, 7/8]$, where $\Sigma_1^+, \ldots, \Sigma_y^+$ are the components of $S \setminus \cup_{j=1}^v A(c_j)$. The tube unions put into the $B_j^\pm$ in $\mathbf{M}_i'$ induce hierarchies on the $B_j^\pm$. Then we get a resolution $\tau_i(B_j^\pm)$ supported on $\Sigma_j^\pm$.

For these resolutions, we can define as follows the first parts of sequences of markings $\mu^-(i,n)$ and $\mu^+(i,n)$ using sequences determined by $\tau(\bar{B}_i)$ and $\tau(\hat{B}_i)$. Each slice in $\tau_i(B_j^-)$ determines a marking on Σ_j^-. We extend markings determined by slices in $\tau_i(B_1^-), \ldots, \tau_i(B_w^-)$ by letting $c_{v+1}, \ldots, c_u$ also be base curves and setting their transversals to be the first vertex on the geodesics supported on $A(c_1), \ldots, A(c_v)$. We move markings by one step by advancing one of the slices in the resolutions of $\tau_i(B_1^-), \ldots, \tau_i(B_w^-)$, not touching $c_{v+1}, \ldots, c_u$. We append a sequence of markings determined by $\tau(B_i^{q+1}), \ldots \tau(B_i^p)$ as in the proof of Proposition 9.1. Similarly, we define $\mu^+(i,n)$ by defining its first part using $\tau_i(B_1^+), \ldots, \tau_i(B_y^+)$, and last vertices on geodesics supported on $A(c_1), \ldots, A(c_v)$.

We also need to modify the definition of the function m. For each μ in $\mu^-(i,n)$, we define $m(\mu)$ to be a point in $\mathcal{T}(S)$ such that a clean marking compatible with μ is a shortest marking in $(S, m(\mu))$, and *the lengths of* $c_{v+1}, \ldots, c_u$ *are equal to those with respect to* m_i. We define m for $\mu \in \mu^+(i,n)$ similarly. Then the rest of the construction in the proof of Proposition 9.1 works without any change. The algebraic limits appearing Claims 9.3 and 9.4 has $c_1, \ldots, c_u$ as parabolic elements since their lengths go to 0 as $i \to \infty$ whatever point you choose on α^- or α^+ by our definition of m as above.

It remains to show that the standard immersion g' does not go around a torus boundary component in $\mathbf{M}'$ in our setting. We consider first the case when Γ is a b-group. Let $\{(G_i, \phi_i) = qf(m_0, n_i)\}$ and $\{(\bar{G}_i, \bar{\phi}_i) = qf(m_0, \bar{n}_i)\}$ be sequences in the Bers slice converging to (Γ, ψ). Let $\mathbf{M}'$ and $\bar{\mathbf{M}}'$ be model manifolds for geometric limits G_∞ and G'_∞ of $\{G_i\}$ and $\{G'_i\}$, which are geometric limits of the model manifolds $\mathbf{M}'_i$ and $\bar{\mathbf{M}}'_i$ constructed as above respectively. Let $g' : S \to \mathbf{M}'$ and $\bar{g}' : S \to \bar{\mathbf{M}}'$ be standard algebraic immersions. Since the lower geometrically finite ends must be lifted to the algebraic limits, neither g' nor $\bar{g}'$ can go around torus boundary components, hence homotopic to horizontal surfaces in $\mathbf{M}'$ and $\bar{\mathbf{M}}'$ respectively. Therefore the argument of the proof of Theorem 8 works, and we see that for any neighbourhood U of (Γ, ψ), there is an arc α_i connecting (G_i, ϕ_i) and $(\bar{G}_i, \bar{\phi}_i)$ in the Bers slice $U \cap B_{m_0}$.

Next suppose that Γ is not a b-group. Let $\{(G_i, \phi_i) \in QF(S)\}$ be a sequence converging to (Γ, ψ). Again, we have only to show that a model manifold $\mathbf{M}'$ of the geometric limit of G_i, a standard algebraic immersion does not go around a torus boundary component. Suppose that g' goes around a torus component T of $\mathbf{M}'$ counter-clockwise. Let c be a longitude of T. Since g' goes around T counter-clockwise, c represents on S an upper parabolic locus of $M_\Gamma = \mathbb{H}^3/\Gamma$.

Since we assumed that Ω_Γ/Γ consists of thrice-punctured spheres, there is either a lower parabolic locus d or an ending lamination λ of a lower end, intersecting c essentially. If there is a lower parabolic locus d, then there is a boundary component T' of $\mathbf{M}$ whose core curve or a longitude is homotopic to $g'(d)$ and which is situated below $g'(S)$. This is impossible since g' goes around T whose longitude intersects d essentially on S. If there is an ending lamination λ, then there is a algebraic simply degenerate end $\Sigma \times (s, t]$ having λ as the ending lamination. Then $\Sigma \times \{s + \epsilon\}$ must be homotopic to $g'(\Sigma)$. Again this is impossible since g' goes around T whose longitude intersects λ essentially on S. Thus, we are lead to a contradiction in either case, and see that g' cannot go around a torus boundary component counter-clockwise. The case when g' goes around a torus boundary component clockwise can be deal with in the same way just by turning everything upside down. $\square$

10. Proof of Theorems 11 and 12

10.1. **Proof of Theorem 11.** After passing to a subsequence, $\{G_i\}$ can be assumed to converge geometrically to a Kleinian group G_∞ containing Γ as before. This induces a pointed Gromov convergence of (M_i, y_i) to (M_∞, y_∞) with $M_\infty = \mathbb{H}^3/G_\infty$. Let $\mathbf{M}$ be a model manifold of $(\mathbb{H}^3/G_\infty)_0$, and $\mathbf{M}_i$ that of $(M_i)_0 = (\mathbb{H}^3/G_i)_0$ as before. As in Lemma 4.4, we take a standard algebraic immersion $g' : S \to \mathbf{M}$. Then $\mathbf{M}_i[0]$ converges geometrically to $\mathbf{M}[0]$ by taking a basepoint x_i in $\mathbf{M}_i$ which is mapped to a point within uniformly bounded distance from the basepoint y_i of M_i.

Let E be an algebraic simply degenerate end of $\mathbf{M}$ with ending lamination λ_E, and $B = \Sigma \times J$ a brick of $\mathbf{M}$ containing E. We assume that E is an upper end. The case when E is a lower end can be argued in the same way by just turning everything upside down as usual. Then by Proposition 4.9, there is a tight geodesic γ_i in $\mathcal{CC}(\Sigma)$ one of whose endpoints converges to λ_E as $i \to \infty$. In the case when γ_i is a geodesic ray, its endpoint at infinity is an ending lamination of an upper end of $\mathbf{M}_i$, which is contained in $e_+(i)$. Therefore, we see that λ_E is contained in the Hausdorff limit of $e_+(i)$.

Next suppose that γ_i is a finite geodesic. Then, by Theorem 3.1 and §6 of Masur-Minsky [27], the last vertex and the $\pi_\Sigma(e_+(i))$ are within uniformly bounded distance, and hence the endpoint of γ_i and $\pi_\Sigma(e_+(i))$ converge to the same lamination λ_E with respect to the topology of $\mathcal{UML}(\Sigma)$. Since λ_E is arational, we see that the Hausdorff limit of $e_+(i)|\Sigma$ contains λ_E.

The converse can be shown by the same argument as the proof of Theorem 5.2. Also, we can show that every upper isolated parabolic locus cannot intersect a minimal component of $e_+(\infty)$ in the same way as in the proof of Theorem 5.2.

10.2. **Proof of Theorem 12.** Suppose, seeking a contradiction, that a sequence $\{(G_i, \phi_i)\}$ as in the statement converges. Let $\mathbf{M}$ be a model of the geometric limit $(\mathbb{H}^3/G_\infty)_0$ as usual. Then by Theorem 11, λ is an ending lamination of an upper end and μ is an ending lamination of a lower end. This implies the shared boundary component of the minimal supporting surface of μ is a parabolic locus which is both upper and lower. This is impossible, and we have completed the proof of Theorem 12.
